ENCYCLOPEDIA OF REMOTE SENSING

Volume Editor

Eni G. Njoku is a Senior Research Scientist at the Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, USA. He has a B.A. from the University of Cambridge, and S.M. and Ph.D. from the Massachusetts Institute of Technology. His research focuses on spaceborne microwave sensing with application to land surface hydrology and the global water cycle. Amongst his awards are the NASA Exceptional Service Medal (1985) and Fellow of the Institute of Electrical and Electronics Engineers (1995).

Aims of the Series

The *Encyclopedia of Earth Sciences Series* provides comprehensive and authoritative coverage of all the main areas in the Earth Sciences. Each volume comprises a focused and carefully chosen collection of contributions from leading names in the subject, with copious illustrations and reference lists.

These books represent one of the world's leading resources for the Earth Sciences community. Previous volumes are being updated and new works published so that the volumes will continue to be essential reading for all professional earth scientists, geologists, geophysicists, climatologists, and oceanographers as well as for teachers and students. See the back of this volume for a current list of titles in the *Encyclopedia of Earth Sciences Series*. Go to <http://www.springerlink.com/reference-works/> and springerreference.com to visit the "Earth Sciences Series" on-line.

About the Series Editor

Professor Charles W. Finkl has edited and/or contributed to more than eight volumes in the Encyclopedia of Earth Sciences Series. For the past 25 years he has been the Executive Director of the Coastal Education & Research Foundation and Editor-in-Chief of the international *Journal of Coastal Research*. In addition to these duties, he is Professor at Florida Atlantic University in Boca Raton, Florida, USA. He is a graduate of the University of Western Australia (Perth) and previously worked for a wholly owned Australian subsidiary of the International Nickel Company of Canada (INCO). During his career, he acquired field experience in Australia; the Caribbean; South America; SW Pacific islands; southern Africa; Western Europe; and the Pacific Northwest, Midwest, and Southeast USA.

Founding Series Editor

Professor Rhodes W. Fairbridge (deceased) has edited more than 24 Encyclopedias in the Earth Sciences Series. During his career he has worked as a petroleum geologist in the Middle East, been a WW II intelligence officer in the SW Pacific and led expeditions to the Sahara, Arctic Canada, Arctic Scandinavia, Brazil and New Guinea. He was Emeritus Professor of Geology at Columbia University and was affiliated with the Goddard Institute for Space Studies.

Preface

During the past few decades, the emergence of remote sensing as a discipline – its science, instruments, missions, and applications – has inspired new and comprehensive studies of the Earth. Detailed observations of Earth's land, ocean and atmospheric processes, and measurements of hitherto unexplored geophysical phenomena have been made possible by remote sensing instruments on ground-based, airborne, and spaceborne platforms. In particular, the unique vantage point of space provides spatially extensive and global perspectives of Earth. Frequent measurements, made hourly, daily, or weekly, over extended periods of years to decades, depending on the observing system and its configuration, have enabled comprehensive studies of Earth's global system. Remote sensing has thus profoundly altered our understanding of the world in which we live, and has revolutionized the approaches we use to study our environment. Each year the growing number of Earth observing satellites, and the increasingly huge amounts of data and information provided, yield new knowledge and greater appreciation of the changes occurring on our planet, with important implications for future generations of Earth inhabitants. This encyclopedia is a comprehensive reference work on Earth remote sensing that presents the foundations, principles, and state of the art of remote sensing and describes the diverse applications it serves. It covers the concepts, techniques, instrumentation, data analysis, interpretation, and applications of remote sensing. This volume is part of the Encyclopedia of Earth Science series and is organized in the same style as other volumes in the series. The scientific disciplines covered by the series have all benefited in one way or another from the new understanding and discoveries afforded by remote sensing. It is thus timely for publication of an encyclopedia that can link these disciplines and the remote sensing techniques relevant to them in an integrated framework.

The focus of the encyclopedia is on remote sensing of Earth – its atmosphere, oceans, cryosphere, and land

surface and subsurface. Some of the techniques described in this volume have their origins in the disciplines of astronomy and astrophysics, and the study of the stars and planets for which, until recently, remote sensing was the only means of obtaining observational scientific data. When applied to Earth, these techniques have blossomed into a remarkably diverse and increasingly sophisticated set of scientific, technological, and computational approaches that all fall under the umbrella of remote sensing. The rapid growth of remote sensing as a discipline is evidenced by the large number of scientific journals now devoted to this field, and the number of courses and degree programs offered at universities around the world. The measurement and interpretation of radiation scattered and emitted by Earth's atmosphere, surface, and subsurface is what we generally mean when we speak of Earth remote sensing. These measurements are obtained by instruments on remote platforms that include satellites, aircraft, balloons, drones, trucks, and stationary towers. Remote sensing instruments take many forms and are designed to measure electromagnetic radiation in specific wavelength regions of the broad electromagnetic spectrum; some instruments use other forms of radiation such as acoustic radiation. Measurements from the wide array of instruments, operating on the variety of available platforms available, can be processed and analyzed to extract characteristic information about Earth and its constituent biological, chemical, and physical structures, at resolutions from centimeters to thousands of kilometers. This remotely sensed information can be used on its own or combined with direct or 'in situ' measurements and geophysical models to give a more comprehensive understanding of the diversity of Earth science phenomena, some of which would be very limited without the unique perspective brought by remote sensing.

It is clear that an attempt to fully cover the breadth and depth of topics in remote sensing is a daunting task. Nevertheless, the need for a compendium that can be used as a reference work for this field, as a living document that

can be updated periodically to capture new advances, is a pressing one. It is with this aim in mind that the Springer *Encyclopedia of Remote Sensing* was conceived. Both this print version of the encyclopedia, which can be updated with revisions once every several years, and an online version, which can be updated on a more frequent basis by authors of individual entries, are provided. The online version can accommodate introduction of new entries as the need for new topics or treatments emerges. The encyclopedia entries cover topics that include broad introductory surveys as well as more in-depth treatment of some subjects. The entries treat topics of the physical principles of remote sensing in different wavelength regimes, propagation and scattering of radiation, geophysical models, remote sensing instrumentation, retrieval methods, remote sensing platforms and observational configurations. The models and retrieval methods are described with reference to specific applications in atmosphere, ocean, cryosphere, land, and solid earth geophysics. These applications include human impacts of climate change, and the enabling interdisciplinary science, as well as applications of direct societal benefit such as human health, food security, and prediction and mitigation of natural hazards. Earth remote sensing from space has flourished in the past few decades, and has become a truly global enterprise through development of international collaborations and partnerships, with investments from an increasing number of countries in building and operating satellite observational systems. Several entries in this volume have been devoted to describing these programs, and associated international policies and principles.

This encyclopedia is designed to support the needs of students, teachers, and professionals across a broad

spectrum of science, technology, and societal applications related to Earth remote sensing. The intended audience includes those with observational interests in the fields of oceanography, atmospheric sciences, meteorology, climate, cryospheric studies, hydrology, geology, solid earth geophysics, ecology, agronomy, forestry, environmental pollution, geography, land use and social studies, among others. The target audience also includes those with interests in remote sensing theory and practice, electromagnetic propagation, radiative transfer modeling, remote sensing instruments, spacecraft systems and orbits, environmental policy and decision-making, resource planning, and monitoring and forecasting of extreme events and natural hazards. In the commercial sector, economists, legal and insurance companies, and commercial and industrial concerns relying on the production, marketing and availability of value-added remote sensing products will also find the encyclopedia a valuable resource. The entries are presented in alphabetical order with titles that are designed to aid searches for specific topics. Cross-referencing using keywords to related entries is also provided to support efficient searches for information of interest to readers. The entries provide bibliographies for further in-depth reading. In summary, though it cannot be claimed that this encyclopedia represents an exhaustive treatment or complete coverage of the field of Earth remote sensing, it is hoped that the volume will serve as a comprehensive and dynamic introduction, and initial entry point, to inspire further reading and study of this exciting and rapidly developing field.

September 2013

Eni G. Njoku

Acknowledgments

A work the size of this encyclopedia inevitably relies on the help and cooperation of a large number of people, only some of whom can be individually identified and thanked here. My particular thanks go to the Board of Section Editors, a group of diverse and highly respected remote sensing scientists. To Mike Abrams, Ghassem Asrar, Frank Marzano, Peter Minnett, Vince Salomonson, Vern Singhroy, and Joe Turk, thank you for keeping this project on course by helping to choose the topics that form the entries, suggesting high-quality authors, reviewing the initial manuscripts, and finally checking proofs with your selected groups of authors as well as writing important contributions yourselves. I also wish to acknowledge the great help of Roberta Balstad, Farouk El-Baz, Moustafa Chahine, Jean-Marie Dubois, A.J. Chen, Robert Gurney, Jim Smith, and Guido Visconti who contributed to the early selection of topics and authors for the encyclopedia. My thanks are due also to Tom Farr who assisted me with the editorial duties during a critical stage in the project.

This leads to the largest group I wish to acknowledge, the authors of the 170 entries that range in size from several hundred words up to major contributions of several thousand words. Many authors took on more than one entry within their specialty area. Due to the length of time required to produce a volume of this type many

authors who submitted entries early had to wait a considerable amount of time before their entries were finally published. To these authors I especially wish to express my thanks for their patience and dedication to the completion of the project, and I hope they find the final volume worth the wait.

At the production end of the project has been the staff of Springer. Their help, understanding, and cooperation, especially when problems needed to be overcome, is something that cannot be appreciated enough. Their patient discussions and exchanges with the authors and board members did much to maintain the smooth progress of the project. Special acknowledgment should go to Petra van Steenberg and Sylvia Blago who provided me with encouragement through many difficult periods, and to Simone Giesler, all of who were involved with the encyclopedia from start to finish. I must also acknowledge the rewarding environment of my host institution and colleagues, all of whom provided a rich source of motivation and ideas in the field of remote sensing to inspire a publication of this type. My final appreciation goes to my wife Mary whose patience and support over the years has been a major factor in my ability to undertake this task, and to my son Eni Jr. who reminds me constantly of the power of positive thinking.

A

ACOUSTIC RADIATION

Alain Weill

Bur. Jussieu, LATMOS, Laboratoire Atmosphere Milieux
Observations Spatiales, Paris, France

Definition

Acoustic. One branch of physics which studies sound.

The word acoustic comes from the Greek word *akoustikos*. “which is related to hearing.”

Sound. It comes from the Latin word *sonum*: “which is related to the hearing sensation created by perturbation of the material medium (elastic, fluid, solid).” In physics, it is a vibration, generally in a gas, created by expansion and compression of gas molecules. Sound waves propagate in the fluid medium and do not propagate in the vacuum. Sounds can be produced in the atmosphere and oceans by living animals or by structures through interaction with the wind, as, for example, trees murmuring, mountains roaring, river sounds, and waves breaking and can be created by various instruments such as music instruments, microphones, speakers, and transducers and also by instruments developed for remote sensing such as SONAR (Sound Navigation and Ranging), ADCP (Acoustic Doppler Current Profiler), and SODAR (Sound Detection and Ranging or what are called echo sounders for atmosphere and ocean). A sound propagating in a medium is characterized by its speed c :

$$c^2 = \partial P / \partial \rho \quad (1)$$

where P is the pressure and ρ the density, and ∂ is derived.

In a gas,

$$c = (\gamma P / \rho)^{1/2} \quad (2)$$

where γ is the heat capacity ratio.

Notice that sound speed in the air for standard conditions of temperature and pressure near the surface is close to 340 m/s, while at the ocean surface it is close to 1,500 m/s, which is faster. This will have an incidence on different ways for acoustic signal processing to be done in the ocean and atmosphere.

Sound or rather a sound wave is a mechanical pressure oscillation, which is generally longitudinally propagating. *Period* T . It is the signal duration corresponding to the time when the sound wave is reproduced identically. *Frequency*. $f = 1/T$ (T in s and f in hertz). *Frequency audio spectrum* (distribution of acoustic energy as function of frequencies can be divided in four zones related to human hearing power: 0–20 Hz infrasound (not audible), 20–300 Hz is low-pitched, 300–6,000 Hz is medium range, 6,000–20,000 Hz is high-pitched, more than 20,000 Hz are ultrasonic sounds (not audible).

Sound amplitude. It corresponds to acoustic pressure fluctuation of the medium Δp (amount of energy in the sound wave) measured at one point of a surface S . It is the ratio of pressure P by the surface element S .

$$I = P / S \text{ in } \text{W/m}^2$$

For a spherical acoustic source, the intensity at distance r is

$$I r = P \text{ (sound power of the source)} / 4\pi r^2$$

Radiation. It is the way acoustic wave energy radiates and concerns acoustic rays from the acoustic sources through

the concerned medium. For example, from a microphone radiating along different directions, we are interested in the radiation diagram corresponding to the knowledge of *rays* (analogy with optical rays) along different directions.

Introduction

We shall begin to analyze (sound) or (acoustic) waves and the wave equation from which we are able to describe energy propagation and rays. If one compares them to electromagnetic waves, acoustic waves are simpler and can be described by the velocity potential, which is a scalar. We shall apply the principles of acoustic wave radiation to different types of acoustic sources used such as monopolar, dipolar sources and the response of the medium at different distances showing that the acoustic field will change of as the characteristics do so. These considerations are really fundamental for remote sensing with acoustic sounders and they are similar to electromagnetic waves, though propagation equations are different. They give information about distances when field characteristics will present some useful organization properties.

Wave equation and acoustic waves in flows

It corresponds to the study of a *plane wave* transmitted in a flow by a vibrating plane. It can be, for example, the diaphragm of a microphone vibrating along an axis x .

A *plane acoustic wave* is a general concept from the physics of waves. It corresponds to a wave where *wave fronts* (surfaces of the same phase) are infinite planes, perpendicular to the same direction of propagation.

The equation of pressure variation p (or wave propagation equation) is

$$\partial^2 p / \partial x^2 = [1/c^2] \partial^2 p / \partial t^2 \quad (3)$$

where, as already said, c is the sound speed.

For a sinusoidal wave, the solution of the equation is

$$p(x, t) = p_0 \cos[(2\pi/T)(t - x/c)] \quad (4)$$

with the wave number $k = 2\pi/T_c = 2\pi/\lambda$ and λ is the wave length.

We get

$$p(x, t) = p_0 \cos(2\pi t/T - kx) \quad (5)$$

where $2\pi/T$ is the *pulsation* ω .

Generally, one uses the complex notation:

$$p(x, t) = p_0 \exp(j\omega t - kx) \quad (6)$$

A linear relation between the displacement gradient (compressibility) gives $p = -\kappa \partial\zeta/\partial x$ (where κ is a coefficient of compressibility) from which we have, solving the sound equation:

$$\partial\zeta/\partial t = (1/(\rho_0 c)) \exp(j(\omega t - kx)) \quad (7)$$

This means that particle velocity is in phase with acoustic pressure.

Other derived definitions are useful parameters for remote sensing techniques as the acoustic impedance Z , which is the ratio between pressure and the complex amplitude of the particle.

To illustrate the interest in using acoustic impedance, in a project for the Titan satellite sounding (Weill and Blanc, 1987), it was suggested to use acoustic impedance from the satellite's surface to discriminate, by acoustic remote sensing, between solid and liquid surface just before a possible crash of the rocket at the satellite's surface.

For the flow, it is equal to $Z_c = \rho_0 c$.

For the plane wave (or *progressive wave*) $\forall x$, we have $Z(x) = Z_c$.

The *condensation* of the wave is the spatial derivative $-\partial\zeta/\partial x$, which corresponds to a relative change of density.

Monopoles, dipoles, and pulsing sphere

If wave propagation Eq. 3 is satisfied, we can work with harmonic solutions of the equation and use wave superposition in the Fourier space. Let us consider one source S of strength q radiating at radial distance r and the solution of the equation for particles radial velocities is

$$v = A (\exp(-jkr)/r^2 + jk \exp(-jkr))/r \quad (8)$$

A is a constant and the boundary conditions are such that the solution vanishes at infinity. It is important to notice that radiation behavior is different as function of distance.

The acoustic flux Fa of the radial velocity v across a sphere of radius is $id v^* 4\pi r^2$ (sphere considered at the distance r) is

$$Fa = 4\pi A (\exp(-jkr) + jkr \exp(-jkr)) \quad (9)$$

Therefore, when kr is small, the first term of (Eq. 9) predominates and the conditions correspond to what is called the *near field* (velocity in phase with the source), and when kr is large, we are in the *far field* conditions (velocity 90° in advance with the source). These very simple statements are very important in acoustic remote sensing, if (for example) active sea foam, which is an acoustic transmitter at the sea surface, has to be modeled; see Vagle and Farmer (1992) to understand acoustic noise below the surface and bubble sound emission.

A more general representation of acoustic sources corresponds to dipolar sources constituting two radiating sources of strengths or magnitudes $q+$ and $q-$ separated by a distance a and such that $m = qa$ is the *dipolar momentum* (as considered in electromagnetism).

Solving the wave equation for the two monopoles with θ the angle between r and the direction of the dipole gives two velocity components: (a) one for the near field (small r): $m(1 + jkr) \exp(-jkr) \cos(\theta)/4\pi r^3$, to which is added a transverse component varying as $\sin \theta$ (orthogonal component), and (b) one for the far field (large r): $-k^2 m \cos(\theta) \exp(-jkr)/4\pi r$, which is typically a radial component. Dipolar sources or a combination of dipolar sources are very useful to simulate acoustic antennas and

Acoustic Radiation, Figure 1 Realization of a three offset antennas for a 6 kHz minisounder. One antenna is *vertical* and two others are *slanting*. One distinguishes compression chambers as acoustic sources and the horns and antennas parts (*parabolic portion* + *circular aperture covered by acoustic foam*).

acoustic sources. Moreover, field analysis considering the distance where the field can be considered as far is very important to interpret, for example, signals coming from *active systems* (which transmit acoustic waves) or *passive systems* (which only receive acoustic waves as *acoustic radiometers* by analogy with electromagnetic and optical radiometers).

Close to monopoles and dipoles, which are theoretical concepts, is the pulsating sphere of radius a . With the condition that $ka \ll 1$, it is shown (for low displacement velocities) that it is equivalent to the radiation of a dipole source at a sphere's center, with radial velocity at the surface equal to $m \cos(\theta) 2\pi a^3$ with $m = 2\pi a^3 U_0$, where U_0 is the amplitude of the velocity. This analogy between dipoles and pulsing spheres is very useful to solve a large amount of questions relative to acoustic environment such as bubble acoustic emission.

A main question in the domain of acoustic radiation and for remote sensing purposes using transmitters and receivers corresponds to antenna design. Acoustic radiation does not concern very thin beams as in the optical domain but rather larger beams, and it is necessary to know precisely beam angles to determine the observation volumes. Once the acoustic source has been chosen as *microphones*, *loudspeakers*, *transducers*, or *compression chambers*, which convert electricity in pressure fluctuations and acoustic waves, we next choose an antenna to transmit and receive acoustic waves through the considered medium.

Different types of antennas are used (as multi-beam antennas, synthetic antennas combining different elementary sources, horn and parabolic antennas), from which several properties of transmitted and received signals must be reached: *directivity*, which corresponds to being able to get a signal in a preferential direction, *antenna beam control*, which concerns the knowledge and design of antenna beam angle and to limit secondary beams to a very low level, as, for example, for atmospheric sounding with SODAR.

For the first acoustic sounders, parabolic antennas have been mainly used; see Neff and Coulter (1986). Though it is easy to theoretically and analytically model such antennas, it often needs heavy computation; see Rocard (1951). A validation of antenna design in an *anechoic chamber* (a shielded room designed to attenuate wave echoes caused by reflections from the internal surfaces of the room), at least to test far-field behavior, is always necessary to qualify the antenna response. This makes necessary the use of large anechoic chambers to realize far-field conditions. Whatever is the antenna design, a perfect knowledge of antenna beam is necessary and will limit unpleasant surprises as important secondary beams or a beam larger than what was wanted could occur.

In Figure 1, we show experimental results obtained from the design of an *offset antenna* for a 6 kHz acoustic sounder controlled in an anechoic chamber. An offset dish antenna is a type of satellite dish. It is so-called offset because the antenna feed is offset to the side of the

Acoustic Radiation, Figure 2 At the top, antenna beam characteristics as measured in an anechoic chamber. At the bottom, a simple schema of the antenna characteristics showing an exponential horn transmitting sound in a portion of parabola.

reflector, in contrast to a typical circular parabolic antenna where the feed is in front of the center of the reflector.

The antenna's characteristics are shown on Figure 2. Notice that if directivity is good and if secondary beams are relatively low, the antenna beam always differs from theory since it is not easy to model all the elements of the antenna and anyway we have always to validate the modeling. However, a beam width of 13° and a receiver gain of 116–126 dB were obtained, which were in fact the objectives of the design.

Conclusion

We have presented elementary elements about acoustic radiation. Of course, acoustic radiation study in the atmosphere and ocean requires deep specific studies, but considering acoustic remote sensing, questions must be mainly summed up to in regard to radiation pattern of

acoustic sources and to antenna design. However, monopole and dipole behavior and also more complicated concepts such as quadrupoles and higher acoustic poles systems, which are not presented here, suggest what kind of questions have generally to be solved.

Definition

Ocean acoustic tomography is a remote sensing technique that employs the transmission of sound over large distances within the ocean to precisely estimate averages of temperature and current. Acoustic tomography data usually consist of time-of-flight travel times of acoustic pulses, which represent natural integrating measures of sound speed and current along acoustic paths. Variations in sound speed are predominantly caused by variations in temperature.

Introduction

Acoustic tomography is a technique for measuring large-scale ocean temperature and current using acoustic signals propagating over 100–1,000 km distances. The technique relies on the nature of the oceanic sound speed profile, which acts as an acoustic waveguide, and the transparency of the ocean to low-frequency sound. Sound speed is

Acoustic Tomography, Ocean, Figure 1 Sound speed at 300 m depth derived from an ocean state estimate from the “Estimating the Circulation and Climate of the Ocean” (ECCO) project. Sound speed is a proxy variable for temperature over most of the world’s oceans.

a function of temperature, salinity, and pressure (Jensen et al., 2011), with an approximate value of 1.5 km/s (Figure 1). Over most of the world’s oceans, the sound speed profile has a minimum at about 1,000 m depth, with sound speed that increases towards the surface as a result of increasing temperature and increases towards the seafloor as a result of increasing pressure. Acoustic signals are therefore trapped in the sound channel by refraction (Figure 2). By recording time series of travel times of acoustic signals, the variability of ocean temperature can be inferred. A typical acoustic arrival pattern consists of a set of 5–15 pulse arrivals spanning several seconds, corresponding to a set of distinct acoustic ray paths. Tomography is a unique measurement in that it is inherently averaging: over range along the path of acoustic propagation and over depth from the cycling of the acoustic signals over the water column. The measurements of large-scale ocean temperatures and currents can be extraordinarily precise.

The concept of acoustic tomography was originally proposed by Walter Munk and Carl Wunsch in the late 1970s in response to the discovery that mesoscale variability in the ocean was intense and ubiquitous (Munk and Wunsch, 1982; Munk et al., 1995; von Storch and Hasselmann 2010). The mesoscale presented a challenging observational problem for oceanography. The proposed answer to this challenge was the in situ integrating measurements of acoustic tomography combined with the near-synoptic measurements of sea-surface height by satellite altimetry. Several acoustic sources and

receivers were to be deployed, forming an array with many acoustic paths crisscrossing a region of interest. The term “tomography” was borrowed from medical tomography, to bring to mind those imaging capabilities. Information available from ocean acoustic tomography is much sparser than from medical tomography, however. From the beginning, the acoustic measurements were to be combined with information from other data types using ocean modeling and data assimilation techniques for optimal estimation of the ocean state (Cornuelle and Worcester, 1996; Menemenlis et al., 1997; The ATOC Consortium, 1998; Rémy et al., 2002; Lebedev et al., 2003).

Sound speed and current

Nominally, a 1 °C change in temperature corresponds to a 4 m/s change in sound speed, while a 1 PSU change in salinity corresponds to a 1.3 m/s change in sound speed. Observed changes in sound speed, measured by tomography through the changes in travel times of acoustic pulses, are therefore ambiguous between temperature and salinity. As a practical matter, however, changes in ocean temperature of 1 °C are common, while changes in ocean salinity of 1 PSU are rare. Other than in extreme environments, the possible effects of salinity changes on acoustic travel times can be ignored.

Ocean currents also affect the time of flight of acoustic pulses, although the magnitudes of current variations are

Acoustic Tomography, Ocean, Figure 2 Top: Sound speed profiles derived from the NOAA 2009 World Ocean Atlas along a 960 km section along 26°S in the Brazil Basin. Middle: Associated acoustic ray paths between a source and a receiver, both at 1,000 m depth. Bottom: Associated ray arrival pattern shown as arrival angle versus travel time. The rays arrive in groups of four, corresponding to the possible signs of the ray angles at the source and receiver. The Brazil Basin has almost ideal characteristics for acoustic tomography. Each region of the ocean has its own unique acoustic properties.

usually an order of magnitude smaller than sound speed variations. The two effects can be separated using reciprocal acoustic transmissions. Reciprocal tomography employs transceivers that transmit coincident signals in opposite directions. The travel times of acoustic pulses with the current will be different than the travel times against the current. By forming the sum and difference of reciprocal travel times, the contributions of sound speed and current can be distinguished.

An early test of reciprocal tomography (RTE87) was conducted in 1987 in the central North Pacific using reciprocal acoustic propagation over ranges of O (1,000 km). Current variations of about 10 mm/s were measured, while sound speed variations were about 25 m/s (Munk et al., 1995). Expressed in terms of acoustic travel times, the nominal time of flight of the acoustic pulses in this experiment was about 600 s, the variations in temperature caused travel time variations of about

0.1 s (summertime warming of the near-surface ocean), and the variations in currents caused travel time variations of about 0.005 s (tidal and low-frequency barotropic currents).

As a corollary to the measurement of current, the integration of currents over the paths of a triangular array of tomographic transceivers is a measure of areal-averaged relative vorticity by Stokes' theorem (Munk et al., 1995). The precision of this measurement can be illustrated by the use of tomography to measure "tidal vorticity" or the changes to relative vorticity primarily induced by the changes in water column depth by tidal elevation. Tidal vorticity of order 10^{-9} s^{-1} , five orders of magnitude less than the planetary vorticity (local inertial frequency), was measured in the western North Atlantic using a pentagonal tomographic array of 660 km diameter deployed in 1991 (Dushaw et al., 1997).

Rays and modes

The determination of information about ocean variability from acoustic data is an inverse problem that requires an ocean model that can be fit to the data using weighted least squares techniques (Munk et al., 1995; Worcester, 2001). Possible models range from a simple time-independent model employing a truncated Fourier series and baroclinic modes to represent horizontal and vertical variability to sophisticated time-dependent dynamical models. The choice of the model depends on the nature of the observed ocean variability and the goals of the oceanographic analysis.

The prerequisite for any inverse problem is a solution for the forward problem, however. Predictions for the acoustic arrival pattern of travel times in any particular experiment geometry can be readily computed by a variety of means, including ray tracing, acoustic modes, or the parabolic wave equation (Jensen et al., 2011). Accounting for a variety of acoustic properties, such as ray travel time and arrival angle, identification of predicted arrivals with measured arrivals is usually unambiguous. This identification is often impossible when the acoustic signals have interacted with the sea floor, however. The tomographic information about the ocean is indicated by the small discrepancies between the predictions and measurements. One goal of this identification is to determine the spatial sampling characteristics, or "measurement kernels," of the acoustics. Most often the measurement kernels are taken to be just the ray paths identified with particular ray arrivals. The measured ray travel times are the integrals of the reciprocal of sound speed along the ray paths. The measurement kernel, combined with the ocean model, enables the essential elements of the inverse problem to be computed, and the weighted least squares solution of that inverse problem gives the desired estimate of ocean variability from the acoustic data.

While acoustic rays have been the measurement kernels most commonly employed for the inversion of

tomography data, acoustic modes have also been employed, particularly in polar regions where the polar sound speed profile confines the lowest modes near the surface. The upper ocean is a region of particular interest, of course. The near-surface modes are also sometimes matched to particular water masses in the Arctic (Mikhalevsky and Gavrilov, 2001).

Recently, "travel-time sensitivity kernels" have been computed, which relate the sampling of the complete acoustic wave field to particular travel times (Skarsoulis et al., 2009). Stemming from this rigorous description of the acoustic field was the important proof, long known in practice, that the measurement kernels computed using the geometric-ray approximation are an accurate representation of the actual sampling associated with particular ray arrivals.

Applications

Over the past 30 years, tomography has been employed for wide-ranging applications (Munk et al., 1995; Dushaw et al., 2010). Several examples that highlight the strengths and roles of the measurement will be mentioned here; more substantive reviews of applications can be found in Munk et al. (1995), Dushaw et al. (2001, 2010), and Worcester (2001).

The Greenland Sea Project deployed a six-mooring tomographic array with 100 km diameter in 1988 in the region of deep convective mixing in the Greenland Sea (Morawitz et al., 1996). The Greenland Sea is one of the few regions where deep water of the world's oceans is formed. The aim of the Greenland Sea Project was to quantify this water formation. Tomography was ideal for this measurement because its remote sensing capability was essential in this harsh, sometimes ice-covered, environment, the quantity measured was the net deepwater formation which is an integrated quantity, and the deepwater formation is episodic and unpredictable in time and location. The rapid sampling of integrated temperature afforded by the acoustic measurements proved to be essential in estimating the net deepwater formation over the winter of 1988/1989. Concurrent, extensive measurements by CTD casts proved to be inadequate to the task.

With the ability to make repeated, integrated measurements along an acoustic path, tomography is often employed to monitor temperature or current averaged across straits or other constricted regions. Mass transport and heat content through the Strait of Gibraltar were measured by reciprocal tomography in 1996 (Send et al., 2002). Temperature variations in Fram Strait are presently monitored by tomography by the multiinstitutional ACOBAR collaboration. Within Fram Strait the complicated West Spitsbergen and East Greenland Current systems transport heat and salt between the North Atlantic and Arctic Oceans. One experiment conducted in the late 1990s by the French Research Institute for Exploration of the Sea (IFREMER) aimed to measure the net transport of heat and salt by subsurface

salt lenses, or Meddies, out of the Mediterranean into the North Atlantic.

With its inherent averaging properties, tomography can make unique, accurate measurements of large-scale barotropic currents. The barotropic currents estimated from the RTE87 data had an uncertainty of about 1 mm/s. Relative vorticity associated with the RTE87 currents was of order 10^{-8} s^{-1} (Munk et al., 1995). Measurements of barotropic tidal currents by tomography are the most accurate available; they have been used to test global tidal models. These capabilities have been underutilized in ocean observation.

Whereas the difference of reciprocal travel times is primarily a measure of depth-averaged current, the sum of reciprocal travel times is primarily a measure of the sound speed signature of the first internal or baroclinic mode. The exact resolution of vertical variability, or resolution of higher-order modes, depends on the available vertical sampling of the rays in any particular region. The inherent depth average of the measurement makes the first baroclinic mode the dominant signal, however, when ocean variability is characterized by baroclinic modes. This property led to the detection of radiation of coherent mode-1 internal tides far into the ocean's interior and placed tomography at the forefront of internal-tide and ocean mixing revolution that has unfolded over the past two decades. One interesting aspect of these observations is that an acoustic path acts as line-segment antenna for the internal-tide radiation. The beam pattern for this antenna has narrow maximum response for wave numbers perpendicular to the acoustic path, corresponding to wave crests aligned along the acoustic path. The culmination of these observations, brought together with the more synoptic observations of these waves by satellite altimetry, was the demonstration that mode-1 internal tides propagate coherently across ocean basins. Tidal harmonic constants can be used to predict the amplitude and phase of the mode-1 internal tides over many regions of the world's oceans (Dushaw et al., 2011).

Over the past 30 years, there have been numerous experiments employing multipath tomography arrays for ocean observation. These experiments have taken advantage of the fact that the number of paths of an array increases quadratically with the number of deployed instruments. Experiments have often consisted of a 5 or 6 mooring pentagonal array, as was the case in the Greenland Sea array (Morawitz et al., 1996), the 1990–1991 Acoustic Mid-Ocean Dynamics Experiment (AMODE) in the western North Atlantic (Cornuelle and Worcester, 1996), and the 1997 Kuroshio Extension Pilot Study array (Lebedev et al., 2003). Other experiments have been deployed in the equatorial Pacific (Kaneko et al., 1996). The 2000–2001 Central Equatorial Pacific Tomography Experiment (CEPTE) was aimed at observing the weak meridional currents of the equatorial current system. These experiments have been designed following the original Munk and Wunsch notion to better understand a complicated region by making sparse tomographic

observations that are combined with all available ancillary data by ocean modeling and data assimilation techniques. These studies have quantitatively shown that the tomographic data type affords a significant resolution of ocean properties not possible by other data types.

Acoustic thermometry of ocean climate

The use of acoustic transmissions across ocean basins to measure the temperature has come to be called acoustic thermometry. These measurements are made possible by lowering the transmitted acoustic frequency to reduce the sound attenuation. With 20–60 Hz sound signals, the range of acoustic propagation in the ocean does not appear to be limited. The aim of these basin-scale observations is to precisely quantify the large-scale changes in ocean temperature (Dushaw et al., 2001, 2010).

One of the first tests of long-range acoustic transmissions for the purpose of ocean climate measurements was the Heard Island Feasibility Test (HIFT). In a 9 day test in 1991, 57 Hz acoustic signals were transmitted from an array of acoustic sources lowered from the R/V Cory Chouest near Heard Island in the southern Indian Ocean (Munk and Baggeroer, 1994). The site is a location with unblocked acoustic paths to both coasts of the United States, and, indeed, the transmitted signals were recorded off the coasts of Nova Scotia and Washington state. The attempts to measure ocean temperatures over antipodal acoustic ranges were then abandoned with the recognition that measurements across several climatological regimes were perhaps less useful than basin-scale measurements.

The HIFT was succeeded by the decade-long (1995–2006) Acoustic Thermometry of Ocean Climate (ATOC) program (The ATOC Consortium, 1998; Dushaw et al., 2009). This program deployed 75 Hz acoustic sources off central California and north of Hawaii to transmit tomographic signals across the North Pacific Basin. The program employed receivers of opportunity and arrays of hydrophones specifically designed to determine the properties of acoustic propagation over several megameter ranges. The acoustic data were used to test accuracy of ocean state estimates of the North Pacific obtained by various means, including simple forward integration of a model, objective analysis of hydrographic and altimeter data, and assimilation of available data to constrain general circulation models. The travel times measured over a decade were compared with equivalent travel times derived from the several state estimates. The comparisons of computed and measured time series provided a stringent test of the accuracy of the large-scale temperature variability in the models. The differences were sometimes substantial, indicating that acoustic thermometry data does provide significant additional constraints for numerical ocean models.

Averages of temperature across the Arctic Ocean were measured in the 1994 Transarctic Acoustic Propagation (TAP) and 1999 Arctic Climate Observations Using Underwater Sound (ACOUS) experiments (Mikhalevsky

and Gavrilov, 2001). These experiments were among the first observations of warming of the Atlantic Layer in the Arctic Ocean. Using acoustics to remotely sense ocean temperature and other properties under the ice is a particularly compelling application of tomography.

Instrumentation

One of the technical advances that made tomography possible was the development of broadband, controlled sound sources in the 1970s to replace explosive charges. By employing lengthy coded signals and pulse compression techniques, the energy of the sound signals is spread over several minutes, while the travel time resolution achieved after signal processing is about a millisecond. The peak pressure of these controlled signals is much less than signals from the explosive sources. Typical sound levels are 25–250 W (or 185–195 dB re 1 μ Pa at 1 m). Low-frequency (75–300 Hz), broadband acoustic sources are large and heavy, however. The size of the source is determined by the acoustic wavelength, which, for 250 Hz signals, is 6 m. One acoustic source commonly used today is a tuneable organ-pipe transducer of about 4 m length and 1,000 kg weight that usually broadcasts a swept-frequency signal from 200 to 300 Hz (Figure 3). Broadband acoustic sources, such as the HLF-5, are also power hungry. Moored acoustic sources powered by lithium or alkaline battery packs can transmit coded signals of a few minutes length several times a day for durations of about a year. Timekeeping is maintained using a rubidium atomic clock. The 75 Hz acoustic sources of the ATOC program were mounted on the sea floor and powered and controlled by a cable to shore.

A tomographic receiver typically consists of a small vertical array of about 4 hydrophones spaced by 1.5 wavelengths. Hydrophone arrays allow for beamforming of the received signals, which boosts the SNR of the acoustic arrival pattern and gives a determination of the ray arrival angles. The arrival angle information is important for matching recorded to predicted arrivals and for distinguishing rays that arrive at about the same time but with different angles (Figure 2, bottom). Tomography transceivers usually consist of a mooring with an acoustic source placed near the sound channel axis and a small vertical line array (VLA) immediately above or below. Both instruments are controlled by a single electronics package.

Recently hydrophone modules were developed with the ability to communicate with a controlling electronics package by induction along the mooring wire. These hydrophone modules allow the deployment of VLAs of any number and spacing, since they can be clamped on the mooring wire at arbitrary locations. For acoustics research, VLAs of 100 or more hydrophones have been employed. These modules include thermistors as well, so that a VLA can act as a thermistor chain. Hydrophones have a broadband sensitivity and of course can also be used for studies of ambient sound.

Acoustic Tomography, Ocean, Figure 3 A Webb Research swept-frequency acoustic source as it is deployed from a ship. The black cylinder is the “organ pipe” acoustic source, and the yellow cylinder is an alkaline battery pack. In the photo the source is horizontal; once deployed the right hand side will be oriented towards the surface. The source is mounted within an aluminum cage for protection during shipping and deployment. Courtesy of Lloyd Green, Scripps Institution of Oceanography.

One extension of tomography is the concept of “Moving Ship Tomography.” The technique aims to make the most of a deployed array of acoustic sources by circumnavigating this array while repeatedly lowering a hydrophone array from a ship to receive the acoustic signals. The aim is to eventually accumulate enough acoustic data that the temperature field within the circumnavigation can be mapped to considerable resolution. Since it can take up to 60 days to circumnavigate a region of 1,000 km diameter, data assimilation techniques are required to account for the evolution of the temperature field while the data are obtained. Recently hydrophones have been experimentally deployed on gliders to receive signals transmitted by tomographic sources.

Passive tomography is an experimental technique that aims to avoid the expense and trouble of moored acoustic sources by using ambient sounds as tomographic signals. The technique employs coordinated receiving arrays deployed on either side of an area of observation. Ambient sound, preferably from such sources as a distant ship or whale, propagating past one array then forms a known signal when it is received on the second array. By comparing the two acoustic signals, information about the intervening ocean might be inferred.

Marine mammals and active acoustics

The HIFT and ATOC programs engendered considerable controversy concerning the possible effects of the transmitted sounds on marine mammals and other marine life (Potter, 1994). The issue presented a formidable challenge in public relations, since it included marine science, climate, and acoustics topics, many of which are still areas of active research. For example, one newspaper report

confused sound levels in air with those in water, which are defined differently, making the underwater acoustic sources appear to be several orders of magnitude louder than they actually were. The sound transmitted by the ATOC sources was 195 dB re 1 μ Pa at 1 m (about 250 W), with a low duty cycle (ca. 2 %) consisting of eight brief transmissions every few days. Because of spherical spreading, 1,000 m from the source the signal level was only 135 dB (about 2.5×10^{-4} W).

As a result of the controversy, the 1996–2006 ATOC and NPAL (North Pacific Acoustic Laboratory) projects included a Marine Mammal Research Program (MMRP) to study the potential effects, if any, of the ATOC sound sources on marine mammals and other marine life. (Indeed, the issue of the effects of acoustics on marine mammals proved to be a boon for marine mammal research.) The MMRP did not find any overt or obvious short-term changes in the distribution, abundance, behavior, or vocalizations of marine mammals in response to the playback of ATOC-like sounds or in response to the transmissions of the ATOC sound sources themselves. The MMRP investigators concluded that the ATOC acoustic transmissions caused no significant biological impact (National Research Council, 2000).

Summary

Ocean acoustic tomography uses the travel times of coded acoustic signals transmitted over 100–1,000 km ranges to infer precise information about the ocean temperatures and currents. In most regions of the world's oceans, sound speed is an accurate proxy variable to temperature; salinity contributions are negligible. One primary strength of the measurement is that it is inherently averaging, suppressing the small-scale internal wave or mesoscale noise that can make it difficult to observe the large-scale signal. Predicted acoustic ray paths can be identified with measured multipath arrivals and used in an inverse analysis to estimate ocean variability. Ray paths have been shown to accurately represent the measurement kernel for the recorded arrivals. The variations of both sound speed and current can be estimated using acoustic transmissions sent reciprocally between transceiver pairs.

Tomography data are perhaps best employed by combining them with other data types, such as satellite altimetry and Argo floats, using data assimilation techniques and ocean models. Such techniques bring together dynamical constraints and disparate data types, each with its own sampling, bias, and error characteristics, to obtain optimized state estimates for the ocean.

Over the past 30 years, tomography has been employed for disparate applications, ranging from the quantification of deepwater formation in the Greenland Sea to the detection of internal-tide radiation from the Hawaiian Ridge to basin-wide measurements of temperature in the central North Pacific. Tomography often requires careful analysis and interpretation, depending on the unique acoustic and oceanographic conditions of the region where it is

employed. Whether used for regional- or basin-scale observations, acoustic remote sensing has been quantitatively shown to provide information about ocean variability that is not possible to obtain by other approaches.

Acoustic tomography was accepted as part of the emerging Ocean Observing System during both of the OceanObs'99 and '09 international workshops (Dushaw et al., 2001; Dushaw et al., 2010). Within the observing system context, the instrumentation for tomography can serve multiple purposes. Hydrophone arrays are used to study a wide range of human, biological, and geological activity. Acoustic sources can transmit signals that can serve other purposes, such as signals that can be used to track drifting instrumentation. Thus, a modest set of active and passive acoustic instrumentation deployed worldwide can form a general-purpose global acoustic observing network (Howe and Miller, 2004; Boyd et al., 2011).

Synonyms

Acoustic propagation; Sound waves propagation

Definition

Propagation. Concerns acoustical wave transmission inside a solid, liquid, or gaseous physical medium without material entrainment.

Introduction

After a very simple description of acoustical geometric propagation and plane wave assumption at large distance from sources, we shall speak about acoustic absorption by the medium as a function of frequencies and medium parameters. Then we shall present Doppler shift, which is very fundamental for remote sensing techniques. We shall be in a position to discuss sound propagation in a stratified media having some mean properties variation as a function of distance of acoustic sources or receivers. This last question is very important for atmosphere and ocean remote sensing where acoustic ray tracing has to be performed to know how acoustic waves propagate and from what kind of target an acoustic signal comes.

Wave propagation

If a pure sound corresponds to a sinusoidal wave, a sound can generally be considered as a superposition of sinusoidal waves of different frequencies f_i .

At the acoustic source 0, we can say that the sound amplitude is

$$y(0, t) = \sum_i (a_i \sin(2\pi f_i t)) \quad (1)$$

If the different frequencies at the origin are considered to be in phase, c the wave velocity is supposed not to depend on frequency.

In the entry on “[Acoustic Radiation](#),” we have described elementary acoustic sources as monopoles, dipoles, and pulsating spheres. Let us consider an acoustical source at one point, which radiates spherical waves. The acoustic intensity at different distances remains the same, considering all of the sphere points at distance r from the source (repartition in the surface $4\pi r^2$), but the acoustic intensity at each point, at the distance r will be divided by $4\pi r^2$. This corresponds to what is called *spherical divergence*. As an easy rule, if the distance is multiplied by 10, the sound intensity will be 100 times smaller.

Notice that far from the source, the wave can be considered as a plane wave.

Wave absorption

Let us consider, as an example, an air layer of depth d and a sound of frequency f_i propagating across this layer. Several observations can be noticed:

If the incident sound has an incident intensity I_{inc} , one part of the sound I_{ref} can be reflected by the layer, one part I_{abs} can be absorbed, and finally one part is transmitted I_{tr} . For the depth d , we can say that the air absorption coefficient corresponds to $a = I_{abs}/I_{inc}$. This absorption coefficient corresponds to absorption at the acoustic frequency f_i .

In the air, sound absorption depends on frequency, temperature, and humidity. A very important reference is Harris (1966), who has performed several laboratory experiments to measure sound attenuation in air (in dB/100 m) as a function of frequency, which is very useful to choose power and frequencies to design acoustic sounders. As the behavior as a function of frequency, of temperature, and humidity is not linear, it is preferable here just to indicate behavior elements and to refer to Harris' (1966) work for precise attenuation evaluation.

It has to be remarked that attenuation grows with frequencies and it presents a maximum, which increases with humidity in percent (maximum of attenuation close to 1 dB/100 m at 2,000 Hz for a typical humidity of 5 % and a maximum of 8.5 dB/100 m for a 20 % of humidity at 25,000 Hz for a temperature of 20 °C).

For humidity between 30 % and 90 %, frequency variation is rather linear (0.3 dB/100 m for 2,000 Hz and 0.8 dB/100 m for 4,000 Hz). Particularly important is to consider that for a chosen frequency, attenuation as function of temperature and humidity in percent presents a maximum, which increases when humidity decreases. Typically, for low humidity below 30 %, attenuation increases as a function of humidity and temperature and for larger temperature (typically higher than 30°), the behavior is reverse and attenuation decreases for higher humidity.

For the ocean, sound absorption is smaller than in the air. It depends on salinity, temperature, and pH (acidity) of the ocean.

Here r is the distance and I_0 is acoustic power transmitted before attenuation. It is close to 0.011 dB/100 m at 2,000 Hz at a 100 m depth. Notice that if the same frequencies as in air are considered for the ocean, wave lengths are, of course, five times larger due to sound speed.

Doppler shift

This very general phenomenon, which is transversal to many remote sensing domains, (electromagnetic, optical, and acoustic), was discovered at the end of the nineteenth century.

For acoustic waves, it corresponds to a frequency shift between a transmitter and a receiver when distances between both change as a function of time. This effect was discovered by an Austrian physicist Christian Doppler in 1842 and confirmed from experiments performed by the Dutch meteorologist Buys Ballot in 1845. Buys Ballot has verified Doppler shift with a special

experimental protocol. Musicians were playing horns on a train of known speed and trained musicians on the railway station were hearing sound changes due to train speed.

If f was the transmitted horn frequency played by musicians, f' the frequency observed by fixed musicians in the railway station, c the sound speed, then the Doppler frequency shift due to the train speed can be written as

$$\Delta f/f = (f - f')/f = v/c$$

where v is train speed.

The observed frequency $f' = f + (fv/c)$ is of course dependent on the relative train velocity.

The Doppler shift is very useful for Doppler Sodar or Sonar to be able, using *distance gates* (surface acoustically illuminated at different distances), to analyze medium properties relatively to observed gates. In fact, with these kinds of instruments, mainly the Doppler spectrum is computed to analyze the mean Doppler shift inside different gates. Radial velocities of the medium, in the case where transmitter and receiver are at the same location (for monostatic systems), are measured.

Reflection and refraction of acoustic waves

It corresponds to a general law of propagation of waves corresponding to the Snell-Descartes- Huygens law used for optical waves. However, ocean and atmosphere are *stratified* in temperature, salinity, current for ocean and in temperature, wind, humidity for atmosphere, which corresponds to the fact that we cannot strictly speak of layers since there are more or less continuous variations of these parameters. Let us consider sound reflection in the ocean. In the ocean, the sound velocity mainly depends on the depth z and one supposes that the surface and the bottom of the ocean are (for a first approximation) horizontal planes. One uses generally the concept of ray approximation, and questions which have to be solved correspond to ray tracing. One necessary (but not sufficient condition) to use this concept is that the relative gradient of sound velocity and the wave length must satisfy (see Brekhovskikh and Lysanov, 1990) the condition:

$$\lambda/c(\partial c/\partial z) \ll 1 \quad (2)$$

We, therefore, apply Snell's law $\cos(\theta)/c(z) = \text{constant}$, where θ is the grazing angle (incidence angle) to vary in thin layers 1,2, ... n , $n+1$, where θ_n , θ_{n+1} , c_n , c_{n+1} are, respectively, grazing angles and sound speeds for layers n , $n+1$.

$$\cos(\theta_{n+1})/c_{n+1} = \cos(\theta_n)/c_n \quad (3)$$

and

$$\cos(\theta_{n-1})/c_{n-1} = \cos(\theta_n)/c_n \quad (4)$$

and so on.

When n tends to infinity, then Snell's law is obtained.

With this type of *discretization* (transformation into small layers) of the atmosphere and ocean, one can obtain

propagation in terms of rays and grazing angles tracing. Notice that layers can be obtained considering variations of the main different ocean parameters (salinity, temperature, current) and for the atmosphere (temperature, wind, humidity).

For a considered layer, we get:

$$\theta = [2(c_2 - c_1)/c_1]^{0.5} \quad (5)$$

Therefore, if c_2 is close to c_1 , θ is very small.

To determine the relationship between the ray curvature and sound velocity gradient, we can use Snell's law in the form

$c_0 \cos(\theta) = c \cos(\theta_0)$, where c_0 and θ_0 correspond to values at a fixed (height or depth).

Differentiating this equation with respect to z gives

$d\theta/ds = -\cos(\theta_0)/c_0 \, dc/dz$ with ds the ray element $= dz/\sin(\theta)$

$\cos(\theta_0)/c_0$ corresponds to the ray path element at a known depth or height.

$\text{Abs}[ds/d(\theta)]$ is the *curvature* ray R .

To find rays across the atmosphere and the ocean is related to different propagation computer programs, which have been mainly developed for ocean acoustics.

It is important to say a word about sound channel, the SOFAR channel discovered by Ewing and Worzel (1948). At a depth which varies with geographical location at about 1 km of depth, rays tend to bend toward regions of smaller sound speed and are channeled. Refracted rays can extend toward thousands of kilometers in range without touching surface or bottom. This propagation channel works like the ionosphere for electromagnetic propagation and plays a fundamental role for low-frequency acoustic communication; see Munk (2002). It has to be noticed that ocean and/or ocean currents modifications, which can be related to climatic variations, can have an impact on this propagation channel. This justifies acoustic studies of global warming, see Munk and Forbes (1989).

For the atmosphere, stratification related to inversion layers, fronts or stratosphere can play a similar propagation layer for acoustic waves as for ocean, but temporal and spatial variability is larger and we cannot speak of a "permanent channel."

Conclusion

Propagation of acoustic waves in ocean and atmosphere knowledge is mainly dependent on properties of these mediums. Acoustic remote sensing is indeed used to analyze atmosphere and ocean behavior or acoustic targets behavior inside these domains as a Doppler shift related to currents or wind, and/or parameters which influence acoustic propagation. Particularly, acoustic *tomography* (analysis by layers (*tomos* in Greek), which is used to invert ocean or atmosphere properties) needs a perfect knowledge of ray tracing modeling with basic principles of ray tracing similar to those shown in this entry.

Definition

Scattering. A way by which obstacles or medium fluctuations of small dimensions can modify acoustic wave propagation in the medium. The difference between scattering processes and the reflection/refraction process is related to acoustic wavelengths. For scattering, acoustic wavelengths are of the order of obstacles and medium fluctuation dimensions. Francisco Maria Grimaldi first described scattering of optical waves in 1665, in the opus *Physicomathesis of lumine*, but this principle was renounced by Fresnel at the end of seventeenth century.

It is important to differentiate between scattering and *diffraction*. Diffraction concerns perturbations whose dimensions are large compared to a wavelength.

Introduction

In the first section, we will describe acoustic scattering by simple obstacles such as spheres. The second section will introduce Lambert scattering and Marsh scattering from surfaces; this process is particularly important for sonar sounding. The third section will introduce acoustic scattering in a turbulent medium; which is useful for understanding propagation in the turbulent atmosphere and ocean. This last process is very fundamental to understanding Sodar (sound detection and ranging) acoustic sounding.

Acoustic scattering of a plane wave on a rigid sphere

Suppose that a plane wave (progressive wave) intercepts a fixed and rigid (not compressible) sphere. As the obstacle is rigid, there is no acoustic emission by the sphere itself and the flow is modified just around the sphere. Here, we use a simple concept of acoustic equivalence to describe acoustic perturbation.

This concept can be summarized as follows.

We examine a small volume (of any shape), and in this case, it is a sphere of shape dimension much less than a wavelength in size. When an acoustic wave intersects the volume, the volume does not transmit any sound since it is not deformed, but it has effects on sound radiation, and sound energy from the incident radiation is scattered in all directions. As in optics, the scattered amplitude is proportional to the wave number at power 4.

1. We have a first perturbation equivalent to a simple acoustic source (monopole) at the center of the sphere that would source and sink sufficient volume to cancel the changes that would occur in its absence.
2. A second perturbation is the same as for a sphere (dipole) oscillating in a medium at rest with a velocity opposite to that of the wave.

Therefore, we can replace the sphere by a single (monopole) and a double source (dipole) located at its center, which has the same effect on the flow at large distances as the sphere did. We assume that $2\pi a/\lambda$ is $\ll 1$, which is equivalent to say that plane wave properties remain constant across the sphere.

This last strict condition on the wavelength and sphere radius has great importance in the choice of wavelengths and frequencies or perturbation dimensions.

The equivalent monopole and dipole will radiate energy in all directions; therefore, the energy in the plane wave will be partially scattered, and we have to evaluate the strength of the equivalent sources.

The change in the incident source is the *condensation* s , which corresponds to the change in volume per unit volume, so the volume compressed into the volume of the sphere is Qs , where Q is the volume of the sphere $4\pi a^3/3$. This would be roughly the same equivalent change for a body of any shape. Hence, the strength of the monopole is the time derivative of this, which gives a strength of $q = -k^2 Q \varphi_0$, q is the strength of the monopole, k the wave number and φ_0 is the source intensity, since the condensation is the derivative of the velocity potential, divided by square of sound velocity in the motion equation. Note that the difference between spatial and temporal derivative is in the factor jk , which makes the difference between temporal and spatial derivative from the wave equation.

The resultant velocity potential from the two equivalent sources acting simultaneously is

$$\begin{aligned} \varphi = & -(ka)^2(2\pi a\varphi_0/3)(2 + 3 \cos(\theta)) \\ & \times (\exp(-jkr)/r) + (ka)(2\pi a\varphi_0) \cos(\theta) \\ & \times \exp(-jkr)/r^2 \end{aligned} \quad (1)$$

where θ is the angle between r and the direction of the acoustic source. The first term is dominant for large distances, since the second term, corresponding to near field, vanishes rapidly.

Consider now the scattered intensity derived from the acoustic pressure; it is proportional to:

1. The intensity of the incoming source
2. $(ka)^4$
3. The sphere surface cross-section
4. $4 + 12\cos(\theta) + 9 \cos(\theta)^2$

This is similar as for electromagnetic waves scattering, except for angular dependence.

Integration in all θ shows an equivalent result, as if the dipole and the monopole were independently radiating. (π in radians is equal to 180°)

If A is the amplitude of the displacement, we get a total scattered intensity:

$$W = (\pi a^2)(\rho c \omega^2 A^2/2) (ka)^4 (4/9 + 1/3) \quad (2)$$

where $4/9$ comes from the monopole and $1/3$ comes from the dipole.

If we divide by the first factor, which is the sphere cross-section, we obtain *the scattering cross-section*.

As for acoustic radiation, monopole and dipole analysis is very useful to simulate scattering if perturbation in the flow can be considered as rigid.

Whatever the different components of the scattered energy are, it is important to notice a strong dependence on wave number at power 4, which means that small wavelengths are more scattered by small obstacles than higher wavelengths.

Lambert's law for a scattering surface

Lambert's law comes from optics and is deduced from observation of scattering by surfaces. It shows that scattering signal is directly proportional to the cosine of the angle θ between the observer's line of sight and the surface normal. The law is also known as the cosine emission law, or Lambert's emission law. In this case, one speaks of *Lambertian* surfaces. It is named after Johann Heinrich Lambert, from his *Photometria*, published in 1760.

This type of scattering is taken into account particularly for analyzing the ocean; for example, scattering from the bottom of the sea, see Urlick (1976).

Let us imagine an acoustic wave intercepting the sea bottom at an incidence θ relative to the bottom.

The surface is supposed to be rough; but at a first approximation, we can think of considering the incidence and the horizontal dimension of the surface such that Snell-Descartes law can be applied.

In fact, the dimensions of surface elements relative to acoustic wavelengths can play a fundamental role, and one finds scattering radiation at angle φ relative to the surface such that if I_{inc} is the incident wave intensity, and dS a surface element, the scattered intensity I_{scatt} is found to be

$$I_{\text{scatt}} = \mu I_{\text{inc}} \sin(\theta) \sin(\varphi) dS \quad (3)$$

where μ is a coefficient of proportionality representative of the surface.

Therefore, we can analyze the relative intensity in dB:

$$P = 10 \log(I_{\text{scatt}}/I_{\text{inc}}) \\ = 10 \log(\mu) + 10 \log(\sin(\theta) \sin(\varphi)) \quad (4)$$

which gives for backward scattering ($\varphi = \pi - \theta$).

$$Pb = 10 \log(\mu) + 10 \log(\sin(\theta)^2) \quad (5)$$

This shows a variation of intensity proportional to the square of the grazing angle sinus.

In a case where transmission across the ocean bottom would be null, it is found by integration that the backscattering strength would be -5 dB.

In a same way, for a bottom transmitting no energy to the medium below, Marsh (1964) has proposed an alternative formula:

$$P = 10 \log[(\sin \theta)^4 k^3 A^2(K) / \pi \cos \theta] \quad (6)$$

where K is a wave number characteristic of the bottom sea roughness, and $A^2(K)$ the bottom-roughness power spectral density.

This expression shows that a rough bottom acts as described by Rayleigh (1878), and it is found that the roughness elements, which contribute to scatter, are related to the incident wave number and the angle θ by the relation $K = 2k \cos \theta$, which indeed has the same behavior as what is called *Bragg scattering* (from the physician Sir William Henry Bragg in 1912, in diffraction of X-rays and neutrons in crystals): enhanced backscatter due to coherent combination of signals reflected from a rough surface having features with periodic distribution in the direction of wave propagation, and whose spacing is equal to half of the wavelength as projected onto the surface.

Of course, same relationships for ocean surfaces are used for acoustic scatter at soil surfaces. The same methods used for acoustics are applied more generally to electromagnetic and optical waves (from radar and lidar) to get information on surface roughness.

The question of scatter by surface is, however, more complicated since, generally, one part of incident wave

is transmitted across the surface, and the transmission depends on surface and subsurface properties; see Urlick (1976).

Acoustic turbulent scattering

The theory of sound scattering from locally isotropic and homogeneous turbulence using the *Born approximation* (use of the incident wave in a homogeneous medium to compute the scattered wave) has benefitted from the conjunction between several researches and discoveries in the recent years: discovery of small-scale turbulence statistical behavior by Kolmogorov (1941), scattering experimental validation by Kallistratova (1959), Monin's (1962) calculation of turbulence spectra for velocity and temperature in the scattering cross-section, and some unification of the question of scattering of waves (electromagnetic and acoustical) in a turbulent medium by Batchelor (1957) and Tatarskii (1961).

The acoustic cross-section of acoustic waves in a turbulent, isotropic, and small-scale medium is

$$\eta(\theta s) = 1/8k^4 \cos^2(\theta s) \\ \times \left[\Phi_T(ks)/T_0^2 + \cos(\theta s/2)^2 E(ks)/\pi c^2 ks^2 \right] \quad (7)$$

described in Batchelor (1957) and Tatarskii (1961, 1971), where η is the differential acoustic cross-section or "reflectivity factor," θs is the angle between scattering and transmitter beam axis, k is the incident acoustic wave number, ks the scattering wave number $= 2k \sin(\theta s/2)$ corresponding to Bragg scattering, T_0 is the mean local temperature in $^\circ\text{K}$, and c is the sound speed.

An inaccuracy in the formula for the dependence of scattering was corrected in Tatarskii (1971), due to the results of Kallistratova (1959, 1960); see Kallistratova (2002).

$\Phi_T(ks)$ and $E(ks)$ are, respectively, the isotropic three-dimensional spectral densities for temperature (for a dry atmosphere) and for turbulent kinetic energy.

Let us remark that if transmitter and receiver are at the same location (monostatic system of observation), only temperature fluctuation spectra contribute to scattering, and if one considers scattering at 90° angle, no scatter occurs in this direction. In the general case, the two spectra contribute to scatter, and we can say, in this case, that we are using a bistatic configuration of observation, transmitting in one direction and receiving in another.

This formulation of scatter of sound by turbulence has been at the origin of the first Sodar by McAllister (1968). An historical and physical discussion of Sodar development can be found in Brown and Hall (1978), and in Neff and Coulter (1986).

Important points to be added correspond to small-scale turbulence definition and what scales of turbulence are responsible for backscatter are responsible:

1. Turbulence scales correspond to the so-called inertial range of turbulence, which for the atmospheric boundary layer typically corresponds to scales ranging from centimeters up to several meters.
2. Acoustic scales responsible for scatter are related to resonant scattered waves satisfying the Bragg relationship, $\lambda = 2 \lambda_s$.

Conclusion

Scattering is a very important process that takes place in the presence of rigid deformations of small scales in the propagation medium, or in the case of surface irregularities and of random perturbations in the medium. Remote sensing of atmosphere and ocean surfaces, therefore, needs a careful understanding and analysis of both medium properties and scattering processes.

Airborne particles; Dust; Particles; Particulate matter; PM; Smoke

Definition

Aerosols are solid or liquid particles suspended in the air, typically smaller in size than a twentieth the thickness of a human hair. There is a subtlety: In traditional aerosol science, “aerosol” refers to the particles and the medium in which they are suspended, whereas in remote sensing, the term often refers to just the particles. We use here the latter definition.

Introduction

Aerosols are of interest due to their impact on climate and health, as well as the role they might play in transporting nutrients and even disease vectors on planetary scales. Particles ranging in diameter from about 0.05 to 10 μm are studied most commonly, as they dominate aerosol direct interaction with sunlight, and are also thought to make up the majority of the aerosol mass. The particles are produced naturally by forest and grassland fires, volcanoes, desert winds, breaking waves, and emissions from living vegetation. Human activities, such as fossil fuel and agricultural burning and altering natural land surface cover, are estimated to contribute about 10 % to the global aerosol load, though these tend to concentrate near population centers where they can have both acute and long-term health consequences.

Aerosols are especially challenging to study because they originate from many, diverse sources and exhibit an enormous range of chemical compositions and physical properties. Unlike long-lived atmospheric gases, airborne particles are typically removed from the troposphere by precipitation or gravitational settling within about a week, so aerosol amount and type vary dramatically on many spatial and temporal scales. For this reason, the frequent global coverage

provided by space-based remote sensing instruments has played a central role in the study of aerosols.

Aerosol remote sensing: the first global observations

The aerosol parameter most commonly derived from remote sensing data is aerosol optical depth. It is a measure of aerosol amount based on the fraction of incident light that is either scattered or absorbed by the particles. Formally, aerosol optical depth is a dimensionless quantity, the product of the particle number concentration, the particle-average extinction cross section (which accounts for particle scattering + absorption), and the path length through the atmosphere. It is usually measured along a vertical path. Particle physical and chemical properties, such as size, brightness, and composition, must also be either measured or assumed, to assess aerosol impact on climate and health. Measuring particle properties remotely remains a major challenge to the field.

Since late 1978, the Advanced Very High Resolution Radiometer (AVHRR) imagers have been collecting daily, global, multispectral data, from polar orbit. These instruments were designed primarily to observe Earth's surface, and data analysis typically included an "atmospheric correction" aimed at eliminating surface feature blurring caused by the intervening gas and particles. However, over-ocean, total-column aerosol optical depth was also deduced, initially from single-channel observations, assuming a completely dark ocean surface in the red band (0.63 μm wavelength) and medium-sized, purely scattering particles.

Global, seasonal, and shorter-term aerosol distributions have been mapped. By associating observed particle concentrations with deserts, wildfire regions, and high-population areas on nearby land, dust, smoke, and aerosol pollution plumes were identified. The AVHRR maps showed that Saharan dust is routinely carried across the Atlantic Ocean and deposited in the Caribbean and, more generally, demonstrated the degree to which aerosols are carried long distances. The observations led to interest in the possible impact of aerosols on the energy balance and hence the climate of the planet, and the role desert dust might play in fertilizing iron-poor remote oceans and the Amazon basin.

Among the limitations of this early work was the inability to separate surface from atmospheric contributions to the observed scene brightness, which precluded retrievals over brighter coastal regions and most land. There was also a lack of direct information about particle properties in these retrievals, and an absence of constraints on vertical distribution, both of which are important for calculating aerosol impacts on climate and health. In addition, it was difficult to distinguish cloud from aerosol signals and, more generally, to assess the accuracy of the reported values. Enormous efforts and considerable

progress were made in each of these areas over the subsequent 25 years.

One way to avoid significant surface contributions to the observed signal is to view the planet edge on, as was done by the Stratospheric Aerosol and Gas Experiment (SAGE) instruments, beginning in 1979. Observing the sun through the long slant path of the atmosphere as the satellite crossed to the night side of Earth, SAGE produced upper atmosphere vertical soundings, which proved immensely effective for monitoring the sulfate aerosols produced in the stratosphere by the Mt. Pinatubo eruption in 1991. But with no more than two occultations per orbit (about 30 per day), and limited ability to sound even as far down as the upper troposphere, other approaches were needed to address key aerosol-related climate and health questions.

Due to the intense scattering of ultraviolet (UV) light by atmospheric molecules, the surface is obscured when viewed from space in the wavelength range 330–380 nm. In the late 1990s, it was realized that the Total Ozone Mapping Spectrometers (TOMS), versions of which had already been orbiting for nearly 20 years, contained the spectral channels needed to retrieve aerosol amount over land as well as water, based on their ability to absorb the upwelling background UV light. This resulted in the Aerosol Index, a qualitative measure of UV-absorbing aerosols such as dust and smoke. The retrieval has limited sensitivity to near-surface aerosols and depends sensitively on the elevation of the particles and their optical properties, but the maps provided the first comprehensive, long-term record of aerosol source regions and overland transports.

One of the first and most widely used aerosol remote sensing techniques is surface-based sun photometry, which involves measuring the varying intensity of the solar disk as the sun changes elevation in the sky. The method predates satellite observations and relies on observing a systematic increase in atmospheric opacity (and the corresponding decrease in solar brightness) as the sun is viewed through longer atmospheric slant paths. Assuming aerosol horizontal homogeneity, column-integrated aerosol optical depth is retrieved, and if this is done at multiple wavelengths, some information about particle size can also be derived.

Beginning in 1991, with the European Space Agency (ESA) two-view-angle Along Track Scanning Radiometer (ATSR) series of imagers exploited the geometrically based approach from space. Unlike sun photometry, the satellite technique measures light scattered by the scene below, so additional assumptions about aerosol and surface optical properties are required to retrieve column-integrated aerosol optical depth. But the atmospheric contribution to the signal still increases systematically, relative to that of the surface, as the slant path increases, making surface-atmosphere separation possible. The steeper slant paths also improve sensitivity to thinner aerosol layers.

In 1996, the first of the French Space Agency (CNES) POLarization and Directionality of Earth's Reflectance (POLDER) imagers began collecting multi-angle, multi-spectral polarization data from orbit. The polarization effects of many types of land surfaces are fairly independent of wavelength, making it possible to separate the more constant surface polarization contribution to the satellite signal from the spectrally varying atmospheric contribution. Aerosols are sometimes divided into two groups, depending on whether their effective diameter is greater or less than a certain size, usually taken to be around 1 μm for satellite observations and 2.5 μm for many health and direct sampling applications. The majority of smoke and aerosol pollution particles, the products of combustion and chemical processing, tend to fall into the smaller or "fine" mode. Mechanically produced desert dust and sea salt particles tend to be weighted toward the "coarse" mode. From its combination of optical measurements, POLDER maps column-integrated fine-mode and total aerosol optical depth over water, as well as fine-mode optical depth overland, and more advanced retrieval algorithms for POLDER data are under development.

Second-generation global measurements

The NASA Earth Observing System's (EOS) Terra satellite, launched in late 1999 into a sun-synchronous orbit crossing the equator at about 10:30 local time, carries two instruments designed in part to make detailed aerosol measurements: the MODerate resolution Imaging Spectroradiometer (MODIS) and the Multi-angle Imaging SpectroRadiometer (MISR). MODIS follows the multi-spectral approach of the AVHRR instruments, but with higher spatial resolution (a maximum of 250 m, compared with up to 1 km for AVHRR), 36 spectral channels, and much higher radiometric calibration accuracy and stability. Total-column aerosol optical depth over global water as well as darker land surfaces is produced routinely every 2 days, along with fine-mode fraction over ocean. Thermal infrared channels are used to detect fires, which can help identify smoke plumes. Efforts are being made to extend the interpretation of MODIS data, for example, by using blue-band data to retrieve aerosol optical depth over bright surfaces (following the TOMS approach) and by developing semiempirical ways of deducing aerosol type from the combination of geographic location, season, and fine-mode fraction. A second copy of MODIS, flying on the EOS Aqua satellite, provides observations similar to MODIS/Terra, at about 1:30 equator crossing time.

MISR complements MODIS, acquiring four-channel, near-simultaneous multispectral views of Earth at nine angles and spatial sampling up to 275 m/pixel. Having a narrower swath than MODIS, MISR takes about a week to image the entire planet. With the multi-angle coverage, aerosol optical depth as well as surface reflectance are retrieved, even over bright desert surfaces. The nine views also sample light scattered in different

directions, which yields some information about column-averaged particle size, shape, and brightness under good retrieval conditions; taken together, the retrieved information makes it possible to map aerosol air mass types, though not detailed particle microphysical properties. From the stereo viewing, MISR also derives the heights of clouds and aerosol plumes near their sources. The injection heights of wildfire smoke, volcanic effluent, and desert dust, produced by stereo imaging, are key quantities used in computer-based aerosol transport simulation models to predict plume evolution and aerosol climate impact.

The most accurate information about aerosol vertical distribution is obtained from lidars, which, unlike passive imagers that collect scattered sunlight, send out their own laser beam as the illumination source. Their ability to detect multiple, very thin aerosol layers, day and night, makes it possible for them to create a global, climatological picture of transported aerosols. But the lidar swath is the width of the laser beam, less than a 100 m in size, so coverage of specific sites or events is serendipitous. The technique was demonstrated in 1994, with the Lidar In-Space Technology Experiment (LITE) aboard NASA's Space Shuttle Discovery, and has been followed by the Geoscience Laser Altimeter System (GLAS) and Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation (CALIPSO) instruments on polar-orbiting EOS satellites. CALIPSO flies in a constellation of satellites called the "A-Train," aimed at making complementary, near-coincident measurements. It includes Aqua carrying one MODIS instrument as well as PARASOL, and the Aura satellite bearing updated versions of POLDER and TOMS, respectively.

The second-generation measurements also represent a new era for assessing the accuracy of satellite aerosol retrieval results. Surface-based networks of autonomous sun photometers, such as the several-hundred-instrument AEROSOL ROBOTIC NETWORK (AERONET) federation, began producing very accurate, uniformly processed time series of aerosol column amount. The results are compared statistically and event by event with the satellite retrievals. By scanning across the sky in addition to making direct sun measurements, the surface stations collect the data needed to derive column-average particle size and brightness as well. Regional surface-based networks of radiometers also contribute to satellite retrieval validation, as well as surface lidar networks such as the NASA's Micro Pulse Lidar Network (MPLNET) and European Aerosol Research Lidar Network (EARLINet).

Despite enormous advances in space- and ground-based aerosol remote sensing, some key measurements elude these techniques. Currently, detailed knowledge of particle composition, brightness, shape, and ability to absorb water is obtained only by collecting samples of the particles themselves. For near-surface aerosols such as urban pollution particles, surface stations are usually deployed, equipped to measure particle size and mass and to acquire samples for chemical analysis. But for more complete

atmospheric characterization, intensive field campaigns are required, involving aircraft, satellites, and ground stations making coordinated observations, often with the help of predictions from aerosol transport models.

Aerosol environmental effects

Most aerosols scatter more than 90 % of the visible light falling upon them, whereas nearly 70 % of Earth's surface is dark water. So overall, aerosols tend to cool the planet by making it more reflecting than it would otherwise be. Climate models play a central role in assessing the magnitude of this effect, as polar-orbiting satellites provide only snapshots of aerosol optical depth and limited information about their brightness, and aerosol data from geostationary satellites, which can make continuous observations of the sub-spacecraft region, are currently only qualitative. For radiative forcing calculations, models simulate the full diurnal cycle, along with uniform, global fields of aerosol amount, brightness, and vertical distribution. Remote sensing observations provide constraints on these models.

Current assessments suggest that the globally averaged aerosol direct radiative effect amounts to a cooling of about 0.1–0.9 W/m², compared to the global warming by carbon dioxide of about 1.66 W/m² (IPCC, 2007). Although the aerosol cooling might offset some greenhouse warming, aerosols, unlike long-lived greenhouse gases, are not distributed uniformly, so their regional effects are far more significant than the global mean. Preliminary assessments of observed trends in aerosol optical depth suggest that since the mid-1990s, aerosol particle pollution has decreased over Europe and eastern North America, whereas it has increased over east and south Asia, and on average, the atmospheric concentration of low-latitude smoke particles has also increased.

In addition to the direct effect they have on sunlight, aerosols play a role in the formation of clouds. Collecting the water molecules needed to make cloud droplets is accomplished with the help of aerosols, called cloud condensation nuclei (CCN). The concentration of CCN in the droplet-formation regions of clouds mediates the number of droplets that form. If a fixed amount of cloud water is divided into more droplets of smaller size, the overall reflectivity of the cloud will be greater. The “first indirect effect” of aerosols on clouds refers to the way increased CCN can lead to increased cloud reflectivity. As smaller-sized droplets are less likely to coalesce into raindrops and precipitate, smaller droplets can also increase cloud lifetime, increasing global reflectivity and slowing the cycling of water through the atmosphere, a process often called the second indirect effect.

Aerosols can weaken or strengthen clouds in other ways as well. If dark aerosols such as soot or smoke are present, they can absorb sunlight and evaporate cloud droplets. Aerosols dissolved in cloud droplets may postpone freezing as droplets are carried aloft in the cores of some types of clouds, invigorating their development. Phytoplankton in ocean surface water might actively

regulate cloud amount by modulating their output of gaseous sulfur compounds, which in turn form sulfate aerosols in the atmosphere and serve as CCN in aerosol-poor skies over remote oceans. It is difficult to test these hypotheses on large scales with currently available measurements, and therefore to assess their environmental impacts, but observations indicate that such mechanisms must at least be considered as part of the global picture.

The magnitude of aerosol indirect effects on clouds is much less certain than that of aerosol direct radiative effects, in part because detailed particle size and composition, which determine their ability to absorb water, cannot be measured remotely with sufficient accuracy. In addition, most CCN are smaller than 0.05 µm, too small to be distinguished from atmospheric gas molecules by remote sensing techniques. The current consensus model-based estimate for global-average indirect effects is cooling of 0.3–1.8 W/m², but with low confidence (IPCC, 2007). Narrowing the uncertainties is likely to require a combination of detailed chemistry and microphysics from aircraft measurements, satellite observations to provide broad statistical sampling, and modeling to generate an overall result.

To date, remote sensing has contributed to our knowledge of aerosol impacts on human health only qualitatively, identifying, with the help of aerosol transport models or lidar profiles, regions where near-surface particle concentrations are especially high. Surface stations are typically more effective in isolating the near-surface aerosols that matter most for these studies, and direct samples are required to provide detailed particle size and chemical composition. However, the spatial coverage of surface stations is very limited. As with climate effects, the future seems to point toward combining satellite and suborbital measurements with models.

Summary

Our appreciation of aerosols' role in climate change has grown over the past 25 years, in part due to the contributions made by remote sensing. First estimates of the impacts transported aerosols have on the atmospheric energy balance, on clouds and the hydrological cycle, on larger-scale atmospheric circulation, and on human health have been made. An understanding has developed for the need to combine detailed physical and chemical measurements from aircraft and ground stations and extensive constraints on aerosol optical depth, type, and vertical distribution from satellites, with numerical models that can simulate present and predict future conditions.

However, much remains to be done. For planning purposes, the accuracy of measurements needed to assess aerosol direct radiative effect must be improved, and uncertainties in aerosol indirect effects on clouds must be reduced. Techniques for systematically constraining models with satellite and suborbital data need to be developed, both to test model parameterizations of aerosol sources, cloud processes, etc., and to assess the

uncertainties in the resulting simulations. Based on past experience, this can be achieved, provided we continue to develop and deploy the instruments, improve the models, and maintain the research community, which have carried the field to this point.

AGRICULTURAL EXPANSION AND ABANDONMENT

Jiaguo Qi

Department of Geography/CGCEO, Michigan State University, East Lansing, MI, USA

Synonyms

Agricultural abandonment; Agricultural expansion; Agricultural land; Change detection; Crop phenology; Mapping agricultural lands

Definition

Agricultural land. Agricultural land may be defined broadly as land used primarily for the production of food and fiber, including croplands, pastures, orchards, groves, vineyards, nurseries, ornamental horticultural areas, confined feeding operations, and other agricultural applications.

Agricultural expansion. The conversion of nonagricultural land use to agricultural use.

Agricultural abandonment. The conversion of agricultural land use to nonagricultural use.

Change detection. The process of identifying and documenting changes in land use over time.

Crop phenology. The study of changes in plant physiology and crop growth stages as influenced by environmental

and anthropogenic drivers, including, for example, seasonal variations in temperature and precipitation.

Mapping agricultural lands. Interpreting remotely sensed imagery to categorize agricultural lands.

Introduction

Agricultural lands are by far the largest land areas that have been intensively managed for food and fiber production. Increases in food and fiber demand have driven significant agricultural expansion over the past decades. The rate and magnitude of agricultural expansion are ever increasing, especially under the recent pressure to develop sustainable energy sources such as biofuels from agricultural crops. Agricultural expansion is the *conversion* of nonagricultural lands to agricultural lands, for example, conversion of forested lands to crops, wetlands to rice fields or fishponds, or natural grasslands to pastures.

At the same time, agricultural lands in many places have been abandoned as traditional agricultural operation has become either unprofitable or impracticable. Agricultural abandonment can be a result of various factors ranging from natural to human. The natural factors may include climate change, such as decline in rainfall or the occurrence of extended periods of drought or flood, which makes traditional agricultural operation practically impossible. In places where agricultural operations rely heavily or exclusively on irrigation, agricultural abandonment may occur due to salinization or reduction in ground or surface water supplies. In some cases, agricultural abandonment happens solely due to economic pressures such as the conversion of traditional agricultural lands into suburban real estate developments near major cities around the world.

Agricultural expansion or abandonment has significant consequences for the economy and food security (Alexandratos, 1999; De La Torre Ugarte et al., 2003; Walsh et al., 2003) as agriculture is the backbone of food supplies. However, agricultural expansion can cause detrimental effects on nonagricultural terrestrial and aquatic ecosystems (Tilman et al., 2001). These environmental consequences include increased soil erosion, nutrient leaching that pollutes aquatic environments and degrades water quality, reduced water availability for other ecological uses, and changes in biogeochemical processes that impact greenhouse gas emissions and soil carbon sequestration.

Whether through expansion or abandonment, agricultural land uses are being altered, and these changes will affect food security, the environment, and future sustainability. The role of remote sensing in agricultural expansion or abandonment is to provide detailed assessments of the spatial and temporal changes of agricultural and nonagricultural lands. Effective monitoring of agricultural expansion and/or abandonment provides timely information for decision makers, economists, and environmental scientists to objectively assess future food security and environmental consequences.

Remote sensing of agricultural expansion and abandonment

Remote sensing has been used as a cost-effective tool to map the spatial extent of agricultural lands (Hogg, 1986; Hall and Badhwar, 1987; Congalton et al., 1998). With multi-temporal remote sensing, agricultural expansion or abandonment can effectively be mapped through change detection analysis. As such, remote sensing of agricultural expansion or abandonment requires a minimum of two images acquired on different dates covering the period for documenting changes in agricultural lands. Two common approaches are utilized for this application: (1) comparison of separately classified remote sensing imagery from two or more different dates and (2) direct, single classification of multi-date remote sensing imagery. These change detection approaches are used to quantify agricultural expansion and abandonment.

Mapping agricultural lands

Agricultural mapping using remotely sensed imagery is a common practice where observed spectral radiance or reflectance is classified into different land use categories. Techniques often employed include supervised and unsupervised classification using various cluster analyses (Haralick et al., 1970; Wharton, 1982; Singh, 1989; Congalton et al., 1998; Steele, 2000; Lucas et al., 2007; Karjalainen et al., 2008). The fundamentals of these classification techniques rely on the fact that different land cover types or crops have distinct spectral reflectance properties and patterns. By analyzing their spectral properties or spatial patterns, similar agricultural lands or crops can be grouped together as a single class (Haralick et al., 1973; Bischof et al., 1992; Vailaya et al., 1998; Benediktsson and Kanellopoulos, 1999).

A recent improvement in agricultural land mapping involves the use of phenological properties of crops. Crop phenological information can be derived from repeated satellite observations, such as the normalized difference vegetation index, that track the changes in plant growth and physiological stage. Because different crops have different phenological properties, such as number of days to reach maximum growth, they can be effectively identified or mapped by analyzing the time series of remote sensing observations (Haralick et al., 1980; Jakubauskas et al., 2002; Wang and Tenhunen, 2004; Chang et al., 2007; Wardlow et al., 2007; Busetto et al., 2008). Use of phenology for mapping crop types is a relatively new application due to the recent availability of frequent, repeated remote sensing observations.

Change detection and assessment

Commonly used techniques of change detection include (a) multi-temporal composite image analysis, (b) image algebra (e.g., band differencing and band ratioing), (c) post-classification comparison, (d) binary masking, (e) spectral change vector analysis, (f) cross-correlation, (g) visual on-screen digitization, and (h) knowledge-based

vision systems (e.g., Singh, 1989; Congalton et al., 1998; Jensen, 2005). For quantitative assessment of agricultural expansion or abandonment, often the post-classification method is used. It requires co-registration and classification of each remotely sensed image. The two classified maps are then compared on a pixel-by-pixel basis using a change detection matrix. This matrix provides quantitative “from-to” land use change information, thereby documenting the total amount of agricultural lands that have either expanded or been abandoned.

Care must be taken for accurate agricultural change detection and assessment. Image processing/interpretation must account for phenological differences of crop systems and differences in spatial resolution, reduce radiometric artifacts from external factors such as atmospheric and substrate conditions, and ensure accurate co-registration of imagery. The accuracy of change detection depends on the effectiveness of all these image processing procedures. Therefore, high-quality image processing and classification is imperative to accurately assess agricultural expansion or abandonment.

Current obstacles to mapping agricultural expansion/abandonment

Agricultural lands are very dynamic, changing rapidly with time. Remote sensing imagery provides information only about the physical attributes of land cover and not on the “purpose” of the lands, or the intentions of the people who manage the lands. For example, forest is a cover type and can be sensed remotely, but whether the forested land is intended for timber harvesting or recreational uses needs to be determined by the owner. A major obstacle in mapping agricultural land use changes is that while remote sensing can identify land cover changes, these changes may not be the result of agricultural land use changes. Successful mapping of agricultural expansion and abandonment is the differentiation of temporary land cover changes (e.g., short-term fallow) from long-term land use changes. Since temporary land cover changes can have the same or similar spectral properties, mapping agricultural expansion or abandonment requires multiple year observations and sufficient ancillary information in order to identify observed changes in land cover as land use changes.

Another obstacle is related to the nature of agricultural lands themselves. Many agricultural crops have similar spectral properties, phenological development, and spatial patterns as nonagricultural cover types. There may be no spectral or spatial pattern differences across these lands even though their uses are different. This can make accurate imagery classification of agricultural expansion/abandonment mapping very difficult.

Conclusion

Agricultural expansion and abandonment is widespread globally and one of the most important forms of land use change. Accurate assessment and monitoring of the rate and spatial extent of expansion and abandonment provides

vital information about the location and availability of agricultural lands for economists, environmentalists, biologists, ecologists, resource managers, and policy makers. Remote sensing provides a cost-effective and repeatable means of mapping and assessing the spatial pattern and rate of change in agricultural land use. With the capabilities of future advanced earth observation systems, such as the *Global Land Observation System* (GLOS) and the *Global Earth Observation System of Systems* (GEOSS), it is foreseeable that timely information about agricultural expansion and abandonment will become available to a much broader user community.

Definition

Reflectance. Light that is returned from the surface of an object in the same wavelength that impinged on the object.

Emission. Emission of energy in wavelengths determined by the Stefan-Boltzmann relationship.

Vegetative index. Combination of wavelengths that are related to a specific canopy parameter.

Canopy parameters. Descriptions of factors that physically define the canopy, e.g., height, leaf area, biomass, yield.

Thermal index. Comparisons of canopy and air temperature that are related to crop water deficits.

Introduction

Agricultural scientists have used remote sensing for hundreds of years to observe plants to assess their vigor or stress from a multitude of factors. These original observations were not made with sensors but with the eye that determined the health of the plant. The calibration process was to compare the affected plant against a standard that the individual had observed before and deemed to be healthy. This type of analysis was possible because there was a change in the color of the leaf which the eye detected as a change from normal and thus different from what was expected. Visual observations remain a viable tool for crop assessment.

Remote sensing in agriculture is possible because of the changes in leaf reflectance throughout the visible, near-infrared, and shortwave infrared wavelengths as shown in Fig. 1. A healthy leaf has a larger reflectance in the green portion of the spectrum with smaller reflectances in the blue and red portions. Leaves are unique in that their reflectance rapidly increases near 0.7 μm and remains high throughout the near-infrared region (Fig. 1). These changes in reflectance allow the leaf to avoid the absorption of large amounts of energy that it would have to dissipate through some means of energy exchange. Light absorbed in the visible regions drives the photosynthetic process. Leaves appear green to our eyes because these wavelengths have the highest reflectance. If our eyes could “see” in the near-infrared wavelengths, leaves

would appear extremely bright because of the high reflectance. Deviations from the expected patterns provide an indication of some level of stress.

The use of spectrophotometers to measure the optical properties of leaves were presented in the early work by William Allen, David Gates, Harold Gausman, and Joseph Woolley who described the basic theory relating morphological characteristics of crop plants to their optical properties (Allen et al., 1969; Gates et al., 1965; Gausman et al., 1969; Woolley, 1971). Their efforts provided detail about high-resolution spectral signatures of natural and cultivated species and were sources of information about normal plant growth and conditions caused by nutrient deficiency, pests, and abiotic stresses (Gausman and Allen, 1973). These research findings help describe, for the first time, the reasons why the spectral signatures of leaves varied from the expected values and the information contained by examining these deviations. Through these basic studies the foundation was formed for what is applied today as remote sensing tools for agriculture. It is not possible to list all of the publications generated by these pioneers in remote sensing but their efforts help develop the basic understanding of leaf reflectance that is utilized today in remote sensing of agricultural crops.

Leaves are not the same as plant canopies and reflectance values for canopies are more complex than individual leaves. Canopies have many different morphological forms because of branch arrangement on trees and vines, leaf architecture and positioning on annual and perennial plants, whether plants are deciduous or evergreen, and how plants are arranged in different planting configurations. Observations of different plants provide an indication of how different canopies reflect light. There is a vast array of potential shapes of canopies, and light interactions with canopies are different than individual leaves. It is this interaction of light with plant canopies that has provided for the value of remote sensing of agricultural canopies and the potential value for using reflectance from different canopies to assess various canopy properties.

The thermal portion of the spectrum represents the longwave radiation and the wavelengths emitted are determined by the Stefan-Boltzmann relationship in which the wavelengths emitted are function of the fourth power of the temperature of the object. Objects on the earth’s surface emit in wavelengths between 8 and 14 μm because of their temperatures being in the range of 300 K. Remote sensing of crop surfaces using infrared thermometers has become routine and offers the potential for crop water stress detection and water management. Similar to the visible and near-infrared research, understanding the importance of thermal radiation for agricultural crops can be traced to original observations by Tanner (1963) who found that plant temperature varied from air temperature and could be measured with thermocouples attached to the leaves. Since that basic discovery, there have been continual advances in the use of thermal wavelengths in agricultural applications.

Agriculture and Remote Sensing, Figure 1 Reflectance of an individual leaf in the visible and near-infrared portions of the light spectrum.

There has been considerable progress in the field of remote sensing and agriculture and the progress was recently documented in Volume 69 of *Photogrammetric Engineering and Remote Sensing* in 2003. The topics covered in this volume were sensor techniques (Barnes et al., 2003), hydrometeorological applications (Kustas et al., 2003), crop management applications (Pinter et al., 2003), crop yield assessment (Doraiswamy et al., 2003), applications to rangeland assessment and management (Hunt et al., 2003), water quality assessment (Ritchie et al., 2003), and sensor development and correction methods (Moran et al., 2003). Another recent review of the application of remote sensing methods to dryland crops was developed by Hatfield et al. (2004) and the advances of remote sensing to agronomic decisions by Hatfield et al. (2008).

Canopy parameters

Observations of canopies provide information about the typical parameters that are observed through other means. These include biomass, leaf area, ground cover, chlorophyll content of the canopies, light interception, grain yield, and crop residue on the soil surface. Each of these parameters provides critical information that can be used to determine if the progression of the crop is at a normal rate or is deviating either in a negative or positive direction away from the normal expectations. It is important to detect how quickly the crop is developing during the season and the size of the plant.

Canopies change throughout the growing season and it is that change that provides the information that can be detected from remote sensing platforms. Agricultural canopies vary in their size, row direction, canopy shape, and even color. Annual crops are different from perennial crops such as orchards or vineyards. Agricultural systems like pastures or rangelands that are permanent grasses or shrubs display large changes throughout the year. It is important to realize that each crop is different, and crop identification has been a primary goal of many remote sensing studies. These crop identification approaches have been used to develop land use maps and crop area for the earth's land area.

Canopy reflectance is different from leaves because of the soil background beneath the crop. Canopy reflectance varies throughout the year, and if we apply the spectral maps to a whole canopy, as compared to an individual leaf, remarkable differences can be observed, as shown in Fig. 2 for a corn crop. There are several important features in this figure that reveal information about the canopy. First, the reflectance of bare soil when there is no canopy is linear and exhibits little difference among individual wavelengths. Second, the variation in the reflectance values for the bare soil is caused by changes in surface roughness induced by either tillage or rainfall events. Third, there is a rapid change in the reflectance values in the visible and near-infrared portions as the canopy begins to develop and grow. Coupled with the rapid increase in the

Agriculture and Remote Sensing, Figure 2 Reflectance across the visible and near-infrared portions of the spectrum for a corn canopy across the year.

near-infrared reflectance values, there is a concurrent decrease in the blue and red and an increase in the green wavelengths. Fourth, there is an equally rapid decline in the near-infrared reflectances as the canopy begins to senesce and the green leaves turn brown. There are very dynamic changes that occur throughout the growing season and these dynamics provide the potential information content from tracking the reflectance patterns of different wavelengths.

Vegetative indices

Vegetative indices (VIs) has been used as a term that describes the relationship of a combination of wavebands or wavelengths to a particular canopy parameter. These VIs range from simple ratios of wavebands to complex empirical relationships of different wavebands or even combinations of different VIs for specific purposes. These have been developed and evaluated extensively over the past 30 years which coincides with the acquisition of reflectance data from the Landsat platforms. These satellites were launched with four broad wavebands that have been extensively used in the development and application of a number of VIs. A summary of the different VIs provided by Jackson and Huete (1991) stated the purpose of VIs was to enhance the vegetation signal while minimizing the solar irradiance and soil background effects. The adjustment for soil background effects is extremely critical in using remote sensing because annual crop canopies and many perennial tree crops are planted in rows. Developing crop canopies do not completely cover or shade the soil; therefore, viewing the crop from above presents a problem in which the signal is a mixture of the bare soil reflectance values and the leaf reflectance. The canopy reflectance is a mixture of both surfaces and VIs need to be sensitive to soil background and be able to compensate for these differences.

Agriculture and Remote Sensing, Figure 3 Seasonal changes in NIR/RED reflectance and normalized difference vegetative index (NDVI) for a maize canopy in central Iowa.

The development of VIs can be traced back to Jordan (1969) who related the ratio of NIR (0.8 μm) to red (0.675 μm) reflectance (NIR/RED) to leaf area index (LAI). Tucker (1979) found it was possible to use red and near-infrared as measures of changes in vegetation over large areas and increased the confidence that VIs had an application for large-scale assessment of crop canopies. He proposed a difference vegetative index (DVI) as NIR-RED. Development of VIs either as ratios of wavebands or linear combinations of wavebands has been primarily through statistical analyses of observed crop parameters and reflectance data. The seasonal trajectory of reflectance from a crop canopy reveals the red reflectance reaching a minimum with increasing leaf area while the near-infrared (NIR) increases (Fig. 2). This causes the ratio to increase as the canopy develops and a range of NIR/RED values from about 1 to over 20. One of the major limitations in the NIR/RED ratio is the lack of sensitivity when the ground cover is low and both reflectance values are similar. Deering (1978) found this limitation could be overcome through the use of a normalized difference vegetative index (NDVI) as shown in Eq. 1.

$$\text{NDVI} = \frac{\text{NIR} - \text{RED}}{\text{NIR} + \text{RED}} \quad (1)$$

The NDVI has been used extensively for the past 20 years as one of the standard VIs for application to crop canopies. It is important to understand the history of VIs and their limitations that were first proposed by the developers of the index. As an example of these limitations is the application of NDVI to various canopy parameters; however, the seasonal trajectory of this index shows a plateau during the vast portion of the growing season because the index becomes saturated at values between 0.9 and 1.0 and when the leaf area index of the canopy reaches values between 3.5 and 4.0 (Fig. 3). When compared to the NIR/RED ratio, there are differences throughout the growing season. Hatfield et al. (1984) evaluated the relationships between LAI, intercepted photosynthetically active radiation (IPAR), and VIs for durum wheat and found that NDVI and intercepted PAR were strongly related. They found that there were two relationships, one for the stage of accumulating leaf area and one for senescing leaf area. This was the first attempt to bring together the NDVI and intercepted light to explain the nonlinear nature of the NDVI and light interception. The comparison of NDVI across multiple data sets by different investigators was summarized by Hatfield et al. (2004). One of the utilities of this approach is being able to estimate intercepted PAR by crop canopies for use in crop growth models for biomass and yield estimates.

Compensating for the soil background in observations of crop canopies has posed a problem for many of the VIs and several modifications to the VIs have been developed to compensate for the soil background. There have been three forms of VIs developed to address the soil background problem. One of the first was proposed by Kauth and Thomas (1976) and used a linear combination of four wavebands using principal component analyses to estimate brightness, greenness, yellowness, etc. “Brightness” represents the magnitude of the reflected energy and could be considered a soil background line. “Greenness” represents an orthogonal plane to the soil line that contained information about vegetation. “Yellowness” is an additional plane to the soil and vegetation lines with particular sensitivity to senescent vegetation. These three parameters provide information content about plant crop canopies during the course of a growing season.

Another method of addressing the soil background was developed in the form of the perpendicular vegetative index (PVI) proposed by Richardson and Weigand (1977) using a statistical relationship given in Eq. 2.

$$PVI = (NIR - aRED - b) / (1 + a^2)^{1/2} \quad (2)$$

To simplify this relationship, Jackson (1983) proposed that PVI could be expressed as:

$$PVI = 0.647NIR - 0.763RED - 0.02 \quad (3)$$

As a further refinement, Huete (1988) developed ratio-based VIs to account for soil background through an approach he termed “soil-adjusted vegetative index” (SAVI) described as follows:

$$SAVI = \frac{NIR - RED}{NIR + RED + L} (1 + L) \quad (4)$$

The L term is an adjustment factor with a value of nearly 0.5 and was added to increase the sensitivity in the separation of canopy and soil at low ground cover amounts. The SAVI index was redefined by Rondeauz et al. (1996) who proposed an optimized SAVI (OSAVI) with the L term set equal to 0.16. Baret et al. (1989) provided an adjustment for soil background to the NDVI as the transformed soil-adjusted vegetative index (TSAVI) described as follows:

$$TSAVI = \frac{a(NIR - aRED - b)}{(RED + aNIR - ab)} \quad (5)$$

where a and b represent empirical coefficients obtained by regression fits to observed data. The changes to the VIs to compensate for soil background demonstrate the path that many VIs have taken toward improving the ability to detect differences in canopy responses.

Vegetative indices provide different representations of canopy parameters and there has been an evolution in these indices with the change from broadband to narrow

wave band or hyperspectral sensors. In many cases there has been a refinement in the wavelengths used in the VI but not a change in the functional description of the index. A summary of the different VIs and their application is presented by Hatfield et al. (2008).

Application to canopy parameters

Leaf chlorophyll content

The greenness of leaves as indicated by their chlorophyll content has emerged as one of the critical parameters in assessing the status of crop canopies. Leaves contain chlorophyll, Chl a and Chl b , essential pigments for the conversion of light energy to chemical energy. Solar radiation absorbed by leaves is a function of the photosynthetic pigment content and directly related to photosynthetic potential and primary production. Changes in leaf chlorophyll content are related to plant stress and senescence. One of the emerging applications of leaf chlorophyll observations is the estimation of the nutrient status because leaf nitrogen is incorporated into chlorophyll. There have been handheld chlorophyll absorbance meters developed to measure leaf transmittance at two wavelengths in the red (0.660 μ m) and near-infrared (NIR; 0.940 μ m) with the theoretical principles of these meters described by Markwell et al. (1995). The principles of the handheld meters have been extended to remote sensing systems that utilize different combinations of wavebands. An example of a canopy-level chlorophyll index is the modified chlorophyll absorption ratio index (MCARI) proposed by Daughtry et al. (2000) as:

$$MCARI = [(R_{700} - R_{670}) - 0.2(R_{700} - R_{550})] \times (R_{700}/R_{670}) \quad (6)$$

This index was developed using three different wavebands that provide information about the chlorophyll absorption at 0.67 μ m relative to the green reflectance peak at 0.55 μ m and the near-infrared reflectance at 0.7 μ m. Using these three wavebands shows the maximum difference in reflectance for a leaf (Fig. 1). A refinement of the MCARI was proposed by Haboudane et al. (2002) as the transformed chlorophyll absorption ratio index (TCARI) that changed the form of the relationship as shown in Eq. 7:

$$TCARI = 3[(R_{700} - R_{670}) - 0.2(R_{700} - R_{550})] \times (R_{700}/R_{670}) \quad (7)$$

Gitelson et al. (2003) showed the possibility of methods to estimate chlorophyll content for plants based on simple ratio of NIR/RED reflectance $- 1$ or NIR/RED_{edge} reflectances $- 1$ and demonstrated the potential of these for canopy level assessments. The MCARI method was found to be sensitive to leaf area index, chlorophyll, leaf area-chlorophyll interactions, and background reflectance (Daughtry et al., 2000) and was especially sensitive to background reflectances when the canopy leaf area was small. Wu et al. (2008) provided a comparison of different

VIs for their ability to detect chlorophyll contents in winter wheat canopies and found the integrated methods that linked VIs sensitive to soil background (OSAVI) with chlorophyll indices (MCARI or TCARI) were the most robust. The estimation of leaf or canopy-level chlorophyll content provides valuable information about the canopy and potential response to nutrient stress or other stress that affects either Chl *a* or Chl *b* formation within the leaf. Zhang et al. (2008) applied these methods to predict the canopy chlorophyll content per unit ground area using hyperspectral sensors. Feret et al. (2008) combined a leaf optical model with the leaf chlorophyll information and leaf reflectance and transmittance to improve the estimation of chlorophyll content for canopies using remote sensing methods. These types of methods provide information about the canopy and are gaining wider use as a diagnostic tool for remote sensing of crop canopies.

Crop biomass

Crop biomass represents the total aboveground accumulation of plant material and is a tangible form of the net primary productivity of crop canopies. Remote sensing has been used to estimate dry matter accumulation or biomass estimation through a combination of NIR and red wavebands. These empirical fits have plant-specific relationships because of the difference in NIR reflectance among species, and this approach requires calibration for each crop and soil combination. There is a stronger relationship to green biomass with the NIR/RED combinations than to total biomass which includes stems, branches, or other nongreen matter.

Other approaches to estimating crop biomass have been to use a conversion factor of intercepted solar radiation to crop biomass using the following form of the relationship:

$$\text{Biomass} = \int \text{PAR} \bullet f\text{IPAR} \bullet \text{RUE} \bullet \Delta t \quad (8)$$

where PAR is the incident radiation, $f\text{IPAR}$ the fraction of intercepted photosynthetically active radiation (PAR) by the canopy, RUE the conversion efficiency of PAR to dry biomass, and Δt the time interval. The estimation of the intercepted values of PAR has taken on many different forms for this approach.

One component of biomass accumulation is the gross primary productivity (GPP) and Gitelson et al. (2006) found that GPP relates closely to total chlorophyll content in maize and soybean. The relationship algorithm for GPP estimation provided accurate estimates of midday GPP in both crops under rainfed and irrigated conditions. This approach has been evaluated using Landsat data to estimate canopy chlorophyll data and photosynthetically active radiation in a combination as proxies for GPP by Gitelson et al. (2012). They found these algorithms were able to estimate GPP accurately at three sites across the Midwest.

Intercepted solar radiation

Estimation of crop biomass is often based on intercepted light by crop canopies and is a critical component in plant growth models. Estimation of light interception by canopies from remotely sensed data would greatly aid in comparing management systems. Intercepted light by a crop canopy can be related to the accumulation of biomass and harvestable grain yield. Daily estimates of intercepted light can be obtained from extrapolation of observations of NDVI combined with daily total PAR obtained from a nearby meteorological station. It is possible to directly compare the performance of different cropping systems using this type of approach with confidence in the results. Observations collected over a wide range of crops and growing conditions suggest that LAI is best obtained from NIR/RED ratios while IPAR is best determined from NDVI.

One of the applications of intercepted light is to determine the rate of senescence of crop canopies. Examination of the rate of change in the NDVI shown in Fig. 3 can be utilized as a tool to examine how quickly plants are losing their physiological functions at the end of the growing season. This approach offers potential to determine if the rates of changes are different than expected and may indicate if there are some factors causing premature loss of green leaves in the canopy. This type of approach is often used for visual determination of premature changes in the canopy and could be easily determined from remote sensing platforms.

Crop ground cover

One of the components that is often evaluated for agricultural applications is the amount of ground covered by the crop canopy and is expressed as the fraction of ground area covered by the projection of standing leaf and stem area onto the ground surface. Changes in ground cover are often indicative of the health of the crop. Determination of ground cover provides a linkage between the growth of the crop and water use patterns of the crop since many evapotranspiration (ET) models use crop cover to relate potential ET to actual ET.

Maas (1998) proposed a method of estimating canopy ground cover in cotton that combined the overall reflectance of the scene and the individual reflectance values from the soil and the crop. He developed the following model for ground cover:

$$GC = (R_{\text{scene}} - R_{\text{soil}}) / (R_{\text{canopy}} - R_{\text{soil}}) \quad (9)$$

where GC is the fraction of ground cover, R_{scene} is the scene reflectance, R_{soil} is the soil reflectance, and R_{canopy} is the canopy reflectance. Scene reflectance is expressed as:

$$R_{\text{scene}} = R_{\text{canopy}}GC + R_{\text{soil}}(1 - GC) \quad (10)$$

He used reflectance values from either red (0.6–0.7 μm) or NIR (0.8–0.9 μm) for these relationships and

found that either waveband could be used. This method of estimating ground cover was independent of location and year. This method was not dependent upon empirical fits of the VI with plant parameters. Estimation of ground cover via remote sensing has proven to be fairly simple and not subject to problems associated with LAI or IPAR. The error in estimates of ground cover using these approaches has been on the order of $\pm 5\%$. This level of error is acceptable for agricultural applications that require ground cover estimates.

Canopy leaf area index

Estimation of the amount of green leaf area of a crop has been one of the primary approaches to understanding crop growth and development and quantifying the effects of different agronomic practices on crop growth. Leaf area index has been used to assess the ability of a plant to intercept light and LAI is used as one of the critical parameters in crop growth models. The NIR/RED ratio was found to be highly correlated with green LAI. However, there was a different form of the relationship of $LAI = a + b \text{ NIR/RED}$ for the growth and senescence portions of the growth cycle. Leaf area estimates for different crops across locations have been summarized by Wiegand and Hatfield (1988) and Wiegand et al. (1990). LAI for wheat was best estimated by the NIR/RED ratio or the TSAVI index using the linear relationships with coefficients of $LAI = a + b \text{ NIR/RED}$ and for TSAVI of $LAI = a + b \text{ TSAVI}$. Estimates of LAI are possible with simple linear models using NIR/RED reflectance. However, there is improvement when the same parameters are used but in a different form, with greatly improved sensitivity. These relationships are valid across a number of crops and agronomic practices within and among locations. To be useful for standard agronomic practices, these relationships need to be calibrated for a specific crop. The multisite comparisons for corn, wheat, and grain sorghum provide a degree of confidence that remote sensing measures can be adequately used to estimate LAI.

There is a relationship between LAI and light interception in plant canopies. One approach that has been proposed for estimating LAI is based on the relationships between fractional cover, f_C , and LAI using a relatively simple exponential relationship (Choudhury, 1987):

$$f_C = 1 - \exp(-\beta LAI) \quad (11)$$

where β is a function of the leaf angle distribution. He estimated β as 0.67 from an average of 18 crops. This method, although robust, has not been applied as often as NIR/RED ratios because the first step in this method is to obtain an estimate of ground cover or fractional cover and then incorporate it into Eq. 11. The multiple steps for this approach have contributed to the more widespread use of the simple regression models between VIs and LAI.

Crop yield

The estimation of green leaf area, intercepted light, or crop biomass is a foundation for the eventual estimation of harvestable crop yield. Yield estimation from remotely sensed data is generally accomplished with either reflectance-based or thermal-based models. These models can be characterized as some form of a relationship between rate of change in the VI and crop growth rate. Considerable variation in the response of the different models across locations has been observed because many of the approaches used empirical fits between yield and remotely sensed data. Deviations from normal grain-filling conditions either by soil, weather, or agronomic practices may not be detectable in simple VI relationships. Grain yields can be related to the rate of crop senescence. Rate of crop senescence can be determined from NDVI or NIR/RED ratios. Crop yield can be estimated from various remote sensing methods and generally involves some method of using the biomass or LAI values obtained from VIs as inputs into either crop growth models to predict yield or direct estimates of yield. Shanahan et al. (2001) used TSAVI, NDVI, and a Green NDVI (GNDVI) where the red reflectance replaced by green reflectance showed an improvement in yield estimation. They found GNDVI provided a slight improvement in yield estimates for the four corn hybrids grown with varying nitrogen (N) and water levels and the utility of this method is the spatial distribution of yield within fields. There continues to be studies reported that relate green, red, NIR, and NDVI values to examine field scale variation in grain yield. In these studies, yield is positively related to NIR and NDVI values and negatively related to green and red values. However, when a comparison is made across the studies there is a large variation in the coefficients in the statistical relationships between VI and grain yield.

There is a need for continued refinement of remote sensing approaches to estimate yield because of the importance in predicting large-scale crop yields or developing field scale maps of yield variation as a part of precision agriculture. One of the areas of potential improvement in yield predictions from remotely sensed observations will occur if we begin to critically evaluate the reasons for the lack of fit between observed and predicted data. Much of the variation can be explained by failure to have field validation data collected at the proper time or incorporation of the improper VIs into these relationships.

Utilization of thermal radiation

Thermal radiation emitted from crop or soil surfaces is representative of the temperature of the surface. However, the utilization of thermally infrared-derived temperatures for assessment of agricultural systems requires a comparison to air temperature. Crop stress methods using surface temperature are based on the comparison with air temperature because of the linkage to the sensible heat exchange of the crop surface. Leaves or canopies that

are cooler than the air temperature have a rapid evaporation rate while those that are warmer than air have a reduced evaporation rate. Plants that have adequate soil water supplies will tend to have leaves cooler than air and as the water supply becomes more limited the leaves will gradually become warmer than the surrounding air. This is premise of all approaches that utilize canopy temperatures that assess crop stress. Unlike the VIs, the use of thermal infrared information has been formed from indices derived from combinations of air and canopy temperatures as empirical relationships to crop yield or biomass based on a comparison to the expected values for a crop in a non-stressed environment. One of the uses of thermal infrared has been the estimation of evapotranspiration from crop canopies.

Variation of the simple canopy: Air temperature difference ($T_c - T_a$) across crops and climates invoked a series of studies that led Idso et al. (1981) to derive an empirical model for canopy stress, while Jackson et al. (1981) derived the more theoretical relationship based on the energy balance of a canopy. The empirical model for CWSI is described as:

$$\text{CWSI} = \frac{dT - \text{MIN}}{\text{MAX} - \text{MIN}} \quad (12)$$

where dT is $T_c - T_a$, MIN is the non-stressed baseline given as $a + b$ (Vapor Pressure Deficit, VPD), and MAX the upper limit of $T_c - T_a$ when the canopy is no longer transpiring. Values for MIN are obtained by measuring T_c throughout a day to obtain the data necessary for the regression equation. Values for MAX are constant across a range of VPDs and are observed in studies in which canopies are not completely water-stressed. The more critical relationship to define in Eq. 12 is the non-stressed lower baseline. Jackson et al. (1981) derived these curves from the relationship as follows:

$$\text{CWSI} = 1 - \frac{E}{E_p} = \frac{\gamma \left(1 + \frac{r_c}{r_a}\right) - \gamma \left(1 + \frac{r_{cp}}{r_a}\right)}{\Delta + \gamma \left(1 + \frac{r_c}{r_a}\right)} \quad (13)$$

where the quantity r_c/r_a is expressed as:

$$\frac{r_c}{r_a} = \frac{\frac{r_a R_n}{p c_p} - (T_c - T_a)(\Delta + \gamma) - (e_a^* - e_a)}{\gamma \left[(T_c - T_a) - \frac{r_a R_n}{p c_p} \right]} \quad (14)$$

and E is actual evaporation, E_p potential evaporation, r_{cp} the canopy resistance of a well-watered canopy, r_c the actual canopy resistance, r_a the aerodynamic resistance to sensible heat transfer, R_n the net radiation, Δ the slope of saturation curve, γ the psychrometric constant, e_a^* the saturation vapor pressure, and e_a the actual vapor pressure of the air. There are differences between Eqs. 13 and 14; however, one can derive the theoretical shape of Eq. 12 from the assumptions of a well-watered and a completely stressed or non-transpiring canopy.

Both of these approaches demonstrated the universal application of these relationships. The crop water stress index (CWSI) has become one of the most widely used methods for quantifying crop stress. The efforts to use these approaches have been summarized in Hatfield et al. (2008).

One of the issues with use of canopy temperatures that is similar to using VIs from reflected radiation is the problem of incomplete canopy cover. In the application of canopy temperatures, the problem of incomplete ground cover is more critical because of the potential differences in the temperatures between the soil and the crop. The use of the average temperature based on a fractional ground cover may not provide the correct average compared to the fractional representation of reflectance values. The development of multiscale approaches that combine thermal, visible, and near-infrared imagery from multiple satellites to partition the fluxes between the soil and canopy offer the potential for future improvements in the use of surface temperature at scales ranging from 1 m to 10 km (Anderson et al., 2007). This type of method shows further refinement in the ability to use remote sensing as an assessment tool for ground-based observations as well as a method for regional-scale measurements.

Application to agricultural problems

Crop nutrient status

Estimation of the crop nutrient status is one of the goals of remote sensing and critical to agricultural production because of the need to optimize crop production relative to the nutrient inputs and reduce the potential environmental impacts from agricultural production systems. The detection of chlorophyll content that was discussed earlier has formed the basis for the development of tools to detect either nitrogen or phosphorus stress in crop canopies. There have been studies that have shown that improvements in nutrient management are possible with remote sensing tools that are calibrated to detection of nutrient stress. These efforts will continue to develop and provide valuable information for management decisions.

Pests and other stresses

There are a variety of potential stresses from a variety of other biotic factors. Detection of biotic stresses using remote sensing is not as advanced as the estimation of canopy parameters. There are a few examples of how remote sensing can detect pests. Riedell and Blackmer (1999) found that aphids (*Diuraphis noxia*, Mordvilko) and greenbugs (*Schizaphis graminum*, Rondani) caused changes in the 625–635 μm and 680–695 μm wavebands because of their effect on leaf chlorophyll status. For this approach to effectively detect stress, a comparison would have to be made to a non-stressed plant. One of the merits of this approach is the ability to detect the

presence of aphids in parts of the field because these insects generally do not uniformly affect a field but occur in isolated areas.

Many leaf diseases cause changes in leaf reflectance and many of these observations have been made for a number of years. One of the early reports was by Blazquez and Edwards (1983) who showed it was possible to detect disease occurrence in both tomato and potato leaves using spectral reflectance. Comparisons that relate disease occurrence, timing, and location information are likely to provide some method of discriminating between disease and healthy leaves at the canopy level. Detection of insects and diseases using a combination of spectral signatures has been conducted at the leaf and canopy scale but the routine extension to the field scale has not been demonstrated.

Weeds within canopies provide another source of confusion with remotely sensed data. These effects are unlike insects or diseases because spectral signatures of weed leaves are similar to crop canopies. Medlin et al., (2000) used green (0.535–0.545 μm), red (0.69–0.7 and 0.715–0.725 μm), and NIR (0.835–0.845 μm) wavebands to detect *Ipomoea lacunosa* L., *Senna obtusifolia* (L.) Irwin et Barnaby, and *Solanum carolinense* L. in soybean canopies. They could detect these infestations within the soybean canopy with 75 % accuracy; however, the greatest difficulty was in the detection of weed-free areas in the field. Their ability to detect weeds was due to differences in reflectance for these wavebands between weeds and the crop. Detection of weeds within various crop and rangeland or pasture canopies has been reported for *Ericameria austrotexana* M. Johnston. (Anderson et al., 1993), *Euphorbia esula* L. (Everitt et al., 1995), and *Chrysanthemum leucanthemum* L. (Lass and Callihan, 1997). Other studies have found only limited success in differentiating crops and weeds because of the similarity of spectral reflectance of weeds and crops (Richardson et al., 1985; Menges et al., 1985). They found they were able to detect plant community areas later in the season due to increased ground cover of weed-crop mixture.

Observations for current research suggest two potential avenues for detection of weeds within crop canopies. First is the direct detection of the weed within the crop by separating the spectral signatures for weeds versus crops. Second is the change in field variability patterns because weeds are not evenly distributed across fields and often aggregate in patches across fields similar to detection of insects or diseases within fields. Both of these approaches have not been extensively explored or evaluated with remote sensing tools. The improvements in both the spatial resolution of reflectance data and the temporal frequency provide opportunities for integrated studies of the remote sensing community with agronomists, weed scientists, entomologists, nematologists, and plant pathologists that will provide new techniques for detection of stresses in crop communities.

Conclusions

Remote sensing for agriculture has had a rich history of providing information about crop canopies. The utilization of reflectance data is enhanced through the incorporation into VIs, and the continual refinement of these VIs for application beyond the estimation of canopy parameters will continue to improve the knowledge base of crop changes throughout the year. The utility of remote sensing to move beyond observation to potential field-scale management by providing more detailed information on the spatial patterns within fields and the value of that information will increase the richness of the data and increase the value for the producer. Increasing the application of these relationships for all crops beyond the agronomic systems and into vegetables, vines, and fruits will require improved understanding of the relationships between reflectance and emittance and canopy parameters. This field continues to evolve and offers the potential for many new areas of investigation.

Air quality

Definitions

Ozone. A gaseous form of oxygen with three atoms per molecule. Ozone is a bluish gas that is harmful to breathe. Nearly 90 % of the Earth's ozone is in the stratosphere and is referred to as the ozone layer. High concentrations of ozone in the lower troposphere make up one of the components of air pollution.

Troposphere. The portion of the atmosphere, which extends outward about 10–20 km from the Earth's surface and in which generally temperature decreases rapidly with altitude, clouds form, and convection and weather are active.

Stratosphere. The region of the Earth's atmosphere extending from the tropopause to about 50 km (31 miles) above the Earth's surface. The stratosphere is characterized by the presence of ozone gas (in the ozone layer) and by temperatures that rise slightly with altitude, due to the absorption of ultraviolet radiation by ozone.

Aerosols. An aerosol is a suspension of fine solid particles or liquid droplets in a gas. Some examples are pollution haze, smog, and oceanic haze.

Introduction

Air pollution refers to increased concentrations of gases or particles that are harmful to human health, vegetation, and welfare. Often, this phrase refers to gases that are regulated as air pollutants by agencies such as the Environmental Protection Agency in the United States. Specifically, the regulated pollutants are ozone, carbon monoxide, sulfur dioxide, nitrogen oxides, lead, and particulate matter. Lead is not measured by remote sensing and will not be discussed here. The study of aerosols with remote sensing is discussed in its own entry under Aerosols.

The Earth's atmosphere is described in layers, starting with the troposphere, which extends from the surface to 10–15 km, depending on location. Since humans and our biosphere occupy only the lowest layers of the atmosphere, much of the focus of studying air pollutants remains on the lowest, near-surface, layers of the troposphere. Still, there is reason to measure all layers of the troposphere, as transport of pollutants and chemical processing occurs throughout the troposphere and can impact the concentrations in the lowest layers. The stratosphere is the layer above the troposphere, and it extends from the tropopause to about 50 km above the surface. Trace gases and pollutants are distributed unequally in Earth's atmosphere, with some pollutants, like CO and SO₂, present at their highest concentrations in the troposphere. Other gases, such as ozone and NO₂, are present in both the stratosphere and the troposphere, so measuring the portion relevant to air pollution requires techniques that differentiate the troposphere and stratosphere. Remote sensing provides the capability to make measurements over a large fraction of the globe but with some limits on our ability to see the chemicals of interest in the troposphere.

This field has matured over the last 3 decades, and there are some excellent overview papers in the scientific literature that provide a history and review (Fishman et al., 2008; Martin, 2008).

This entry reviews total column measurements of CO and ozone and then discusses approaches to measure tropospheric ozone and CO. Finally, other tropospheric pollutants, namely, SO₂ and NO₂, are discussed. Note that this entry was written in 2010 and reflects the measurements up to that point in time.

Measurement of total columns of pollutants

The Measurement of Air Pollution from Satellites (MAPS) experiment was flown on the Space Shuttle four times between 1981 and 1994, and using infrared channels, it provided the first global views of CO concentrations. The technique of the Measurement of Air Pollution from Satellites (MAPS) measurement (correlation radiometer in the infrared) is most sensitive to enhancements in the mid- to upper troposphere. Measurements taken over 8–10 day periods clearly showed the high CO concentrations that came from biomass burning activities in October of 1984 and 1994, and the April 1994 measurements showed that there was some enhancement of CO across the whole Northern Hemisphere (Connors et al., 1999; Reichle et al., 1999).

A number of sensors have been used to make global measurements of CO with similar wavelengths and similar vertical sensitivity. The Japanese infrared instrument, Interferometric Monitoring of Greenhouse Gases (IMG), made global CO measurements for several months in 1996–1997 (Hadji-Lazaro et al., 1999). The Measurements of Pollution in the Troposphere (MOPITT) instrument on NASA's EOS Terra was launched in 1999 and

now has over 10 years of CO measurement data (Deeter et al., 2003). The Atmospheric Infrared Sounder (AIRS) instrument on EOS Aqua, Tropospheric Emission Spectrometer (TES) on EOS Aura, and Infrared Atmospheric Sounding Interferometer (IASI) on CNES/EUMETSAT's METOP platform have all demonstrated CO measurements from infrared channels (McMillan et al., 2005; Rinsland et al., 2006; Clerbaux et al., 2009).

In addition to CO measurements, the total column of ozone has been measured from space for decades. The Total Ozone Mapping Spectrometer (TOMS) instrument was flown in 1978, with a focus on measuring the total column ozone and contributing to our understanding of the polar ozone holes. A number of techniques have been developed to make an estimate of the amount of ozone in the stratosphere (generally from limb sounders) and take the difference of the total column ozone and the stratospheric amount to get an estimate of the tropospheric ozone. This is generally referred to as the tropospheric ozone residual (see Fishman et al., 1990) and was originally applied to TOMS total columns and SAGE stratospheric profiles. This technique has been adapted to use other column measurements (such as the Ozone Monitoring Instrument (OMI)) and other stratospheric estimates (such as MLS). While this technique provided some of the first global views of the tropospheric ozone distribution, it has limited sensitivity to the ozone in the lower troposphere.

Measurements of tropospheric ozone

An innovation in the measurement of tropospheric pollutants, especially ozone, came about with the EOS Aura Tropospheric Emission Spectrometer (TES). The TES instrument measures with very high spectral resolution (0.1 cm^{-1}) in the infrared, which allows for differentiation of tropospheric and stratospheric ozone. In cases where the surface temperatures are warm and there is a large amount of ozone, TES can differentiate the amount of ozone in the upper and lower troposphere (Worden et al., 2007; Jourdain et al., 2007). TES has provided global views of tropospheric ozone, and with the simultaneous CO measurements, the data has been used to estimate the impact of large biomass burning events on tropospheric pollution (Logan et al., 2008) and of the long-range transport of anthropogenic pollution (Zhang et al., 2006).

Ozone retrievals from infrared measurements with coarser spectral resolution (AIRS and IASI) have shown very limited sensitivity to ozone below 300 hPa (Pittman et al., 2009). A number of research algorithms have been applied to the IASI data for ozone profile retrievals, with some differences in sensitivity and biases, but they consistently show limited sensitivity below 5 km (Keim et al., 2009).

A methodology to retrieve tropospheric columns of ozone directly from satellite measurements in the ultraviolet and visible has been reported (Chance et al., 1997). This technique was demonstrated with global retrieval of tropospheric ozone column from the Global Ozone

Mapping Experiment (GOME) satellite data in Liu et al., (2006). GOME (Burrows et al., 1999) was launched aboard the European Space Agency (ESA) European Remote Sensing satellite ERS-2 in 1995. This technique requires a good estimate of the tropopause height and can have limited sensitivity to lower tropospheric ozone. This technique has since been applied to the SCanning Imaging Absorption spectroMeter for Atmospheric CHartographY (SCIAMACHY) and GOME-2. SCIAMACHY (Bovensmann et al., 1999) was launched aboard ESA's Envisat in 2002, and GOME-2 (Callies et al., 2003) was launched aboard ESA's MetOp-A in 2006. Most recently, it has been applied to the NASA EOS OMI data (Liu et al., 2009).

Measurements of tropospheric CO

The MOPITT instrument was designed to exploit both thermal infrared (TIR) and near-infrared (NIR) absorption features of CO. In principal, the use of these two bands together should provide better discrimination of the tropospheric distribution of CO, providing more sensitivity to the surface than any other measurement of CO. Although MOPITT has been making measurement with both of these bands, it has been difficult to use the NIR measurements, but progress has been made on this front (Deeter et al., 2009). Recently (Worden et al., 2009), CO retrievals that combined the TIR and NIR measurements from MOPITT have been demonstrated, and they do show more sensitivity to the surface.

Other pollutants: NO₂ and SO₂

Nitrogen dioxide (NO₂) is present in the stratosphere and troposphere, but because of significant tropospheric sources and a lifetime in the troposphere that is a day or two, the variability of NO₂ is driven by tropospheric variability. This has allowed satellite measurements of NO₂ to be used to estimate the tropospheric column, by making an adjustment for the stratospheric amount, based on the column over a clean region (generally over the central area of oceans). As with ozone, this technique has been applied to many satellite measurements – GOME, SCIAMACHY, and OMI (Martin et al., 2002; Richter and Burrows, 2002; Beirle et al., 2003; Boersma et al., 2004; Bucsel et al., 2006).

Sulfur dioxide (SO₂) has been measured from a variety of UV remote sensing instruments, including TOMS (Krueger, 1983; Krueger et al., 1995), SBUV/2 (McPeters, 1993), GOME (Eisinger and Burrows, 1998), OMI (Carn et al., 2007; Yang et al., 2007; Krotkov et al., 2008), and SCIAMACHY (Lee et al., 2008). The first sulfur dioxide measurements were of volcanic eruptions, and that is the focus of most remote sensing measurements. Volcanic SO₂ is often injected into the upper troposphere and lower stratosphere in large eruptions, and this provides a strong signal in comparison to the background. Eisinger and Burrows, (1998) showed that they could measure tropospheric sulfur dioxide enhancements due to coal burning

power plants. Emissions from copper smelters and power plants have been measured with OMI (Krotkov et al., 2008), which has two orders of magnitude improvement in the minimum detectable SO₂ mass relative to TOMS, due to a smaller footprint and improvements in the wavelengths used in the retrieval.

Conclusions

A number of remote sensing techniques have been developed to detect and quantify key air pollutants in the troposphere. Using ultraviolet, visible, and infrared wavelengths, many species have now been measured over a number of years. More recently, TES on EOS Aura has demonstrated that with high spectral resolution in the infrared, stratospheric ozone can be differentiated from tropospheric ozone, and under polluted conditions, the upper and lower tropospheric ozone can be differentiated. Recent work on MOPITT data has shown that CO measurements with sensitivity near the surface can be extracted from using the 4.6 and 2.3 μm bands together.

Acknowledgment

The research to prepare this entry was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with NASA.

Definition

Atmospheric general circulation models (atmospheric GCMs) are mathematical models based on numerically discretized versions of differential equations that describe the atmospheric physics and dynamics, which are utilized to simulate the global atmospheric circulation. Atmospheric GCMs have several practical applications including medium-range (typically 3–10 days) [weather forecasting](#), (see entry [Weather Prediction](#)), seasonal forecasting (typically 3–12 months) when coupled to models of other components of the climate system such as the global ocean, and climate prediction (typically 10–1,000 years) when models of the various components of the climate system, such as sea and land ice, carbon-cycle, and biosphere models, are incorporated.

Introduction and short history

Atmospheric general circulation models are based on the fundamental fluid dynamics and thermodynamics equations that govern the transport of momentum, energy, water mass, and chemical species in the atmosphere. The essential fluid dynamics and thermodynamics equations were formalized during the nineteenth century leading to the Navier–Stokes equations, the energy conservation equation, and the introduction of the Coriolis effect in the momentum conservation equations.

When meteorological weather forecast services were established around the world in the second half of the nineteenth century, their practitioners were often compared with their astronomical colleagues, who could accurately predict celestial events such as eclipses and the return of comets. However, weather forecasters, relying on empirical rules and experience, often had difficulties in accurately predicting next day's weather.

In the early twentieth century, Vilhelm Bjerknes (1904), proposed that weather prediction should be based on the fundamental equations of fluid dynamics and energy conservation. Accordingly, weather could, in principle, be predicted along the same lines as the motions of celestial bodies.

In 1922, L. F. Richardson (Richardson, 1922) publishes a groundbreaking book on numerical weather prediction where he basically sets up the agenda for the entire field and describes in detail an example of a forecast. However, and besides the fact that his forecast appeared as fairly inaccurate, it was quite clear that the amount of required

numerical computations, if done by humans, was impossibly large in operational terms so as to be able to produce forecasts much faster than the real weather. In order to overcome this problem, Richardson envisioned a future where thousands of “human calculators” would be working together in a single room producing weather forecasts for the whole world.

The situation changed dramatically with the advent of computers after World War II, when John von Neumann thought of weather prediction as one of the most obvious applications of the new tremendous numerical power provided by computers – in fact, von Neumann was not as interested in weather forecasting per se, as he was interested in computational models of the atmospheric general circulation. During this period, a substantial amount of research was carried out in creating the field of numerical analysis of differential equations. In the mid-1950s, Norman A. Phillips developed the first [general circulation model](#) of the global atmosphere (e.g., Randall, 2000).

Model dynamics

Modern global weather and climate prediction models are made up of several component models (i.e., atmosphere, land, ocean, ice). The models of the atmospheric component, or atmospheric GCMs, have two main building blocks: (1) model dynamics, representing the large-scale motions of the Earth’s atmosphere, and (2) model physics, which includes a suite of parameterizations of sub-grid-scale physical processes (see below). It is the dynamical core’s role to solve the partial differential equations that describe the large-scale motions. The heating, cooling, and mixing processes represented by the model physics appear as forcing terms in these equations. Errors in both the model physics and dynamics can have significant impacts in terms of weather and climate predictability.

Atmospheric dynamics are well approximated by numerical solutions of the Navier–Stokes equations, but as in almost all fluid dynamics applications, this approach is far too computationally expensive because of the large spectrum of scales present in global weather and climate prediction problems. Atmospheric GCMs use modified equations, which still capture important features of atmospheric dynamics, such as cyclones, anticyclones, frontal zones, and jet streams while neglecting inconsequential processes for weather and climate forecasting such as acoustic waves (see entry [Acoustic Waves, Propagation](#)). A common choice are the atmospheric *primitive equations*, which also neglect small terms related to spherical geometry, small terms related to the Coriolis effect, and some small vertical acceleration terms (the hydrostatic approximation).

The computational domain of a GCM is the thin spherical shell containing the Earth’s atmosphere. One of the defining characteristics of a dynamical core is how it handles this spherical domain. The grids used in GCMs

are constructed by decomposing a three-dimensional grid into a two-dimensional grid for conforming to the surface of the sphere (the *horizontal grid*) and a one-dimensional grid in the radial direction (the *vertical grid*). For the horizontal grid, there are three main approaches all of which have strengths and weaknesses.

One approach is to use a mesh of equally spaced points in latitude and longitude. These grids are highly structured but have a severe clustering of grid points at both poles, creating some numerical challenges collectively referred to as the pole problem. There are many effective numerical treatments of the pole problem, one of the most successful being the spherical harmonic expansions used by global spectral methods, but they often degrade parallel scalability (the ability to efficiently use multiprocessor computers in order to speed up the numerical solution of the equations).

A second approach is to decompose the sphere into several regions, each of which is meshed with a quasi-uniform grid without poles. The resulting grids must be stitched together, using a composite or overset grid method. This stitching process can make it difficult to numerically conserve mass and energy in a physically consistent way.

The third approach is to use an arbitrary tiling of the surface of the sphere with polygons, usually spherical triangles, quadrilaterals, or a combination of hexagons and pentagons. These grids are challenging for finite difference methods and are most effectively utilized by finite element and finite volume methods designed for fully unstructured grids. The choice depends on the application needs in terms of accuracy, numerical conservation properties, and parallel scalability.

Model physics

The problem of physical parameterization in fluids is as old as the first modern studies of turbulence in the nineteenth century. It was apparently clear from the start, at least to some, that for turbulent fluids, such as the atmosphere, it is not feasible or even relevant to try to follow every parcel of fluid in its turbulent trajectory. Instead, it was suggested from the early twentieth century that research should concentrate on trying to understand the statistical properties of turbulent flows.

The numerical discretizations in weather and climate prediction models imply a limit for the temporal and spatial scales below which the fluid motions cannot be resolved by the model. Because of the nonlinear nature of the atmosphere, the unresolved small scales can have a fundamental influence over the resolved large scales. Since there is no way of explicitly knowing in detail what happens at the sub-grid scales, the physics at these scales has to be parameterized as a function of the resolved motions. What can be estimated about the model variables at scales smaller than the horizontal grid scale are their statistical properties such as joint probability density functions (PDF) within the grid box. Ultimately, for

turbulence and convection, the essential problem of parameterization is how to estimate these PDFs at every model grid point.

It is natural to divide atmospheric physics parameterizations into two main groups: (1) the parameterization of radiation and cloud microphysics and (2) the parameterization of convective and turbulent mixing and associated cloud structure. Radiation and cloud microphysics parameterizations represent physical interactions that occur at extremely small scales from the atomic and molecular scales to cloud droplet scales. Turbulence and convection parameterizations, as discussed before, attempt to represent in a large-scale, atmospheric flow that occurs at scales smaller than the typical grid size (on the order of 10–100 km in the horizontal) of atmospheric GCMs. As such, they do represent fundamentally different physics and are often treated using different mathematical and conceptual tools.

Overall, in modern atmospheric GCMs, there are several different physical processes that need to be parameterized, which are traditionally classified as *follows*: turbulence or boundary layer parameterizations that represent sub-grid vertical motions within the boundary layer (i.e., the region of the atmosphere where turbulence is most prevalent, from the surface to about 1 km height); moist convection parameterizations that represent sub-grid vertical flow due to convective motions driven by condensation/evaporation processes associated with convective towers; cloud parameterizations that represent sub-grid clouds and condensation/

evaporation processes, including cloud microphysics; longwave and shortwave radiation; interactions with the ocean and land surface; and sub-grid orographic effects (e.g., gravity wave drag). More detailed information regarding atmospheric general circulation models in general, and model physics and dynamics in particular, can be found in Haltiner and Williams (1983), Randall (2000), and Washington and Parkinson (2005).

C

CALIBRATION AND VALIDATION

Andreas Colliander
Jet Propulsion Laboratory, California Institute of
Technology, Pasadena, CA, USA

Definition

Calibration. The process of quantitatively defining the system responses, under specified conditions, to known, controlled signal inputs. The result of a calibration permits either the assignment of values of measurands to the system output or the determination of corrections with respect to the system output (Joint Committee for Guides in Metrology JCGM (includes ISO) 2008; Randa et al., 2008; CEOS Working Group on Calibration and Validation, 2012).

Validation. The process of assessing, by independent means, the quality of the data products derived from the system outputs. The quality is determined with respect to the specified requirements (Joint Committee for Guides in Metrology JCGM (includes ISO) 2008; Randa et al., 2008; CEOS Working Group on Calibration and Validation, 2012).

Introduction

The value of remotely sensed data products, in the scientific sense in particular, is determined by how well the characteristics of a product are known (e.g., Platt and Sathyendranath, 1988; Wentz and Schabel, 2000; Atlas and Hoffman, 2000; Jung et al., 2010). These characteristics generally include long- and short-term deviation of the product value from the true value corresponding to the measurement, which is estimated through independent means (e.g., Wehr and Attema, 2001), and accuracy of the geographic location assigned to the product

(e.g., Wolfe et al., 2002; Small et al., 2004). The process of determining these characteristics for a particular remote sensing product is referred to as validation. However, before a data product is validated, it needs to be calibrated. Therefore, the calibration and validation processes are very closely linked together although they are distinctively two separate processes (see the Definition). This entry discusses calibration and validation in terms of characterization against the true value; geolocation aspect of the validation is a separate topic with specific challenges and solutions.

Remote sensing missions have requirements for the data products they are tasked to produce (e.g., Barre et al., 2008). The aim of the calibration and validation process of a particular mission is then to show that it meets its stated requirements (e.g., Delwart et al., 2008). Since the requirements are typically assigned based on expected scientific utilization of the data, the calibration and validation processes are generally regarded as a scientific function. Furthermore, the science community commonly contributes to calibration and validation efforts of data products independently from the missions in their research, due to the importance of knowing the characteristics and quality of the data (e.g., Donlon et al., 2002; Wang and Key, 2003; Mears and Wentz, 2005; Flanner et al., 2010).

The challenges of calibration and validation are specific to the mission and the data product. However, there are some general challenges concerning most of the remote sensing products. The most common and general issues causing concern are (1) establishment of accurate reference sites where the true value corresponding to the measurement can be estimated independently and accurately (e.g., Cosh et al., 2004) and (2) representing the entire measurement domain, which is often global, with a finite number of these sites (e.g., Morisette et al., 2002). It is typical the calibration and validation effort of a given mission

continues during the entire lifetime of a mission and even beyond (e.g., Xu and Ignatov, 2010).

Remote sensing data products can be divided into sensor products and geophysical products. Sensor product refers to output of an instrument after translating the instrument counts to a desired quantity, such as normalized radar cross section (e.g., Srivastava et al., 1999) or radiance (e.g., Abrams, 2000). Geophysical products refer to data products which contain geophysical parameters, such as wind speed (e.g., Liu et al., 1998) or leaf area index (e.g., Yang et al., 2006), retrieved based on the sensor products (and usually with some additional ancillary data). The calibration and validation of the sensor and geophysical products differ in some aspects and are discussed separately in the subsequent text.

International cooperation is in a key role to satisfy the requirements of calibration and validation of typical remote sensing products with very large domains. Committee on Earth Observation Satellites (CEOS) (CEOS Working Group on Calibration and Validation, 2012) is one international organization which has been active in promoting calibration and validation efforts. The Working Group on Calibration and Validation of CEOS has formulated a general approach for calibration and validation of remote sensing products and has established a validation hierarchy based on different stages of extent of validation efforts (see the end of this text).

Historical perspective

At the beginning of the satellite remote sensing era (e.g., Nimbus-1 in 1964 and Landsat-1 in 1972), the calibration and validation activities were mostly limited to activities carried out directly by the space agencies. The current form of utilization of remote sensing data products started roughly with the launch of NASA's Nimbus-7 satellite in 1978. The new data policy of this mission enabled engagement of wider science community in more rapid manner after the launch of the satellite (Goddard Space Flight Center, National Aeronautics and Space Administration 2004). This also contributed to the start of the community-wide pre-and postlaunch calibration and validation efforts of remote sensing data products (e.g., Austin, 1980; Hovis, 1982; Stowe, 1982; Bernstein and Chelton, 1985; Stowe et al., 1988). After this, most NASA Earth observation satellites have followed the similar data policy. However, other space agencies have highly varying policies regarding data dissemination, which directly affects the extent of the calibration and validation activity.

Currently, it is common that a launch of each new remote sensing instrument initiates the science community to seek opportunities to participate in the calibration and validation activities. Naturally, the increased number of instruments and accumulated experience on the calibration and validation of satellite data products is another main reason for the increasing activity in the calibration and validation front. However, the calibration and validation efforts of remote sensing products have maintained

very similar features from the earlier days of remote sensing (e.g., compare (Hilland et al., 1985) with (O'Carroll et al., 2008)). At the same time, new instruments and new applications do require new methods for successful calibration and validation of remote sensing products.

Sensor products

Calibration and validation of the sensor products of a mission is the critical part in ensuring the usefulness of the mission data. The quality of the sensor products typically dominates the quality of the geophysical products. Each remote sensing instrument has an algorithm which is used to translate the raw instrument counts to the desired quantity. The complexity of the algorithm depends on the instrument implementation and the properties of the desired quantity. For example, retrieval of normalized radar cross section requires measurement geometry in addition to instrument parameters (Ulaby et al., 1982), whereas antenna temperature of radiometer is independent of the measurement geometry (Ulaby et al., 1981). In principle, the features of the algorithm dictate the requirements for the calibration effort (i.e., parameters to be adjusted), and the quantity itself determines the requirements for the validation effort (i.e., proper target representing the quantity).

Instrument calibration usually includes some sort of internal calibration sources (e.g., Xiong and Barnes, 2006; Brown et al., 2007). While these sources can be used to remove the effects of some instrument non-idealities, they do not provide reference for the full instrument measurement chain (e.g., Butler and Barnes, 1998). There are different approaches for external calibration: use of an onboard reference target (e.g., Yamaguchi et al., 1998; Twarog et al., 2006); measurement of celestial targets, such as moon or cosmic microwave background radiation (e.g., Sun et al., 2003; Jones et al., 2006); or establishment of a reference target on the ground. Dedicated efforts to improve the stability of the observations (e.g., Gopalan et al., 2009; Eymard et al., 2005) and studies to correct errors caused by the antenna of an instrument (e.g., Njoku, 1980; McKague et al., 2011) are also typical for calibration of remote sensing instrument. Intercalibration between the remote sensing instruments is an important aspect for extending a data record either in time, to lengthen the time series and/or increase the fidelity of the time series, or in space to increase coverage (e.g., Cavalieri et al., 2012; Xiong et al., 2008).

There are areas on the surface of the Earth which provide well-defined response for some types of remote sensing measurements. Therefore, the target on the ground may be a natural scene suitable for calibration purposes (e.g., rain forests for microwave scatterometers (Long and Skouson, 1996)) or it can also be a target built for this specific reason (e.g., corner reflector for synthetic aperture radar (Shimada et al., 2009)). Some of the natural targets can provide relative well-defined absolute reference

value; others are more suitable for just tracking stability of the instrument. Examples of Earth scenes used as vicarious references for spaceborne remote sensing instrument calibration are Antarctica ice sheets (e.g., Macelloni et al., 2007, 2011), Amazon rain forests (e.g., Shimada, 2005), oceans (Ruf et al., 2006), deserts (e.g., Slater et al., 1987), and dry lake beds (e.g., Helder et al., 2010). Utility of man-made structures has also been demonstrated, such as a large asphalt field in Biggar et al., (2003).

Validation of sensor data products is usually done by using on-ground reference targets discussed above, since this represents the relevant measurement plane for the scientific utilization of the measurements. After the sensor product has been calibrated, it is compared against selected targets to establish the uncertainty of the product. This process may lead to further calibration too in which case the residual deviation from the targets becomes the result of the validation. Ideally, of course, the targets used for calibration and validation should be different. However, the use of the same targets is the reason why sometimes the nomenclature of sensor cal/val process refers only to calibration and does not include references to validation, even though it is clearly part of the process.

Geophysical products

The retrieval algorithms of geophysical parameters are highly varying in their approach to determine the value of the desired parameter. Regardless of the approach, however, each algorithm requires calibration in order to optimize the correctness of its output. In order for the calibration process to be successful, the structure and error contributions of the algorithm need to be known (e.g., Pulliainen et al., 1993; Keihm et al., 1995; Wentz, 1997; Njoku et al., 2003; Brando and Dekker, 2003). Several algorithms include forward models that require detailed calibration before application to the inverse processing (e.g., Wigneron et al., 2007). In order to accomplish the calibration of an algorithm field, measurements and additional remote sensing measurements are typically exploited to determine the parameter values of the algorithm (e.g., Kelly et al., 2003; Njoku et al., 2003).

The validation process of geophysical products requires knowledge of the true value of the geophysical parameter within the effective measurement area with uncertainty less than the required uncertainty of the product. The following subsection discusses the issues related to scaling the in situ truth measurement to the footprint scale in spatial domain. Even in the absence of the spatial scaling issues, the uncertainty of the actual in situ measurement must be less than the uncertainty requirement of the product (e.g., Emery et al., 2001; Bailey and Werdell, 2006; Henocq et al., 2010). The establishment of these validation sites depends naturally a great deal on the geophysical parameter: The general approach and requirements for wind speed (e.g., Dobson et al., 1987) or chlorophyll a (e.g., Ruiz-Verdu et al., 2008) measurement are completely different from snow water equivalent

(e.g., Tedesco and Narvekar, 2010) or leaf area index (e.g., Garrigues et al., 2008) measurements, let alone atmospheric water vapor (e.g., Divakarla et al., 2006), or ozone (e.g., Froidevaux et al., 2008) measurements. The objective in each case is nevertheless the same, to find a representative measurement of the parameter so that it can be compared against the remotely sensed value. After appropriately matching up the remotely sensed product and the in situ measurement, the validation results are typically presented as, for example, root mean square error, correlation, and histograms (e.g., Hooker and McClain, 2000; Bourassa et al., 2003; Hilland et al., 1985).

Spatial scaling

Remote sensing measurements are based on the instrument recordings of interaction of electromagnetic waves with the target. The instruments have a defined sensing area or volume (i.e., footprint) depending on the antenna beam shape and interaction of the measurement signal with the sensed medium. When it comes to calibrating and validating the measurements, the independent reference measurements, in situ measurements in particular, typically do not have the same features as the remotely sensed signal and do not measure the exactly same domain as the footprint represents. The translation of the reference measurements to the remote sensing footprint is often referred to as spatial scaling, and it is a crucial part of the calibration and validation of remote sensing products. Sensor product calibration and validation efforts usually try to utilize homogeneous regions where scaling is not an issue in the same way as with calibration and validation of typical geophysical products.

The challenge of the spatial scaling depends typically on the relationship between the heterogeneity of the measured parameter and the size of the footprint. Scaling of even relative high-resolution (small size) footprint may be challenging for highly heterogeneous parameters (e.g., Liang et al., 2002). Some remote sensing instruments have very low resolution, but if the measured parameter changes slowly over large distances, scaling can be accomplished with relative few resources within the footprint (e.g., Le Vine et al., 2007). The most challenging cases include of course remote sensing measurements of highly heterogeneous parameters with large footprints (e.g., Jackson et al., 2010).

There are several techniques developed for scaling the value of geophysical parameters up to the footprints of remote sensing measurements. As an example, these techniques include aggregation of in situ measurements (e.g., Jackson et al., 2010), model-based techniques (e.g., Chen et al., 1999), timing of the acquisition so that the heterogeneity effect is minimized (e.g., Wang et al., 2008), and temporal stability approach which assumes that single point of the area represents the footprint average (e.g., the challenge then is to find the representative point (Vachaud et al., 1985; Grayson and

Western, 1998)). An important aspect of the upscaling of the in situ measurements is estimation of the error associated with the upscaled value. Several techniques have been proposed and used for accomplishing this, for example: investigating the variance of the subscale measurements (e.g., Tian et al., 2002) and combination of several observation sources (e.g., Hilland et al., 1985; O'Carroll et al., 2008; Caires and Sterl, 2003; Miralles et al., 2010).

Coverage

Although it is generally accepted that the validation of the geophysical products should be done against in situ measurements, other references are being applied too. The reason for this is that in general, in situ measurements have limited coverage in space and in time, i.e., they do not cover the entire domain, which is often global (the main reason why remote sensing is applied in the first place), and it may not always be possible to make in situ measurements for long periods or with high frequency for a certain location (e.g., consider limitations of radiosondes, dropsondes, and buoys).

Depending on the size of the covered domain, the challenge for the calibration and validation effort is to find a strategy with which it can be claimed that the product is calibrated and validated over the entire domain. Therefore, other remote sensing sources (e.g., Corlett et al., 2006) and models (e.g., Caires and Sterl, 2003) have been used to complement the in situ measurements. It is also typical to divide the entire domain in sub-domains and then find validation sites which represent each sub-domain (e.g., Hilland et al., 1985) or to cover a diversity of conditions with set of sites which can be claimed to represent the conditions over the entire domain (e.g., Ceccato et al., 2002). But only rarely a validation is accepted without some strategy to reference the measurements back to verifiable in situ acquisitions.

Temporal context

Remote sensing products can be calibrated and validated over a short time period (a few years at most) or a long time period (at least a decade). Calibration and validation of individual missions is usually a short-term effort because the mission requirements are typically set without long-term requirement and, furthermore, the duration of a single mission is seldom long enough to qualify as a long term anyway. Therefore, long-term calibration and validation imply inter-mission effort to extend the calibrated and validated data record to over decade long time frame (e.g., Gallo et al., 2005). Typically high quality long-term data records are required for climate applications (e.g., Flanner et al., 2011; Behrenfield et al., 2006), but also other monitoring and tracking applications require long-term remote sensing observations (e.g., Lepers et al., 2005). The type, quality, and length of remote sensing data records have limited the use of remote sensing data for long-term applications until more recently.

The requirements of calibration and validation process are affected significantly by the climatic temporal context of multiple decades combined with usually very high requirements on the stability. Therefore, a combination of both retrieval intercomparisons and in situ measurements is often necessary to validate the long-term record (e.g., Takala et al., 2009). For example, the importance of [sea surface temperature \(SST\)](#) record for climate studies was understood long time ago (e.g., Harries et al., 1983) and ever since significant effort has been made to establish a well-calibrated long-term SST record (e.g., Stuart-Menteth et al., 2003).

Prelaunch calibration and validation

It is common that remote sensing missions include calibration and validation activities for both sensor and geophysical retrieval algorithms in the prelaunch phase. Essentially, the objective of these activities is to increase the expectation of the mission success to the level that launching a satellite seems worthwhile. Missions set requirements for the instrument performance based on the intended use of the measurements. In the prelaunch phase, this performance is verified through measurements, analysis, and simulations. The calibration strategy of an instrument may require measurement of certain calibration parameters on the ground, and sometimes, when possible, the instrument is entirely calibrated on the ground already. These activities are often referred to as prelaunch calibration activities. However, it should be emphasized that the eventually applicable calibration is almost always conducted on the orbit.

The development of geophysical retrieval algorithms starts before mission definition in research activities which try to identify potential remote sensing measurements concepts. The prelaunch calibration and validation activities include similar components as retrieval algorithm research such as field campaigns and simulations. However, these activities are driven by particular mission characteristics such as exact observation configuration including measurement frequency, footprint, coverage, and instrument performance figures. The prelaunch efforts can only approximate the actual measurements of the mission, and the actual calibration and validation of the retrieval algorithms and products takes place only after the launch of the mission.

Validation stages

CEOS (CEOS Working Group on Calibration and Validation, 2012) has put forward a four-stage validation hierarchy which has been adopted by many data providers. The validation stage increases with increasing product maturity and extensiveness of the validation effort.

- Stage 1 validation: Product accuracy is assessed from a small (typically <30) set of locations and time periods by comparison with in situ or other suitable reference data.

- Stage 2 validation: Product accuracy is estimated over a significant set of locations and time periods by comparison with reference in situ or other suitable reference data. Spatial and temporal consistency of the product and with similar products has been evaluated over globally representative locations and time periods. Results are published in the peer-reviewed literature.
- Stage 3 validation: Uncertainties in the product and its associated structure are well quantified from comparison with reference in situ or other suitable reference data. Uncertainties are characterized in a statistically robust way over multiple locations and time periods representing global conditions. Spatial and temporal consistency of the product and with similar products has been evaluated over globally representative locations and periods. Results are published in the peer-reviewed literature.
- Stage 4 validation: Validation results for stage 3 are systematically updated when new product versions are released and as the time series expands.

Summary

All remote sensing products require calibration and validation, and it is an essential part of the process of making remote sensing products to meet the requirements of scientific utilization. The main challenges in the calibration and validation of almost any data product are how to make corresponding and representative reference measurements and how to extend the validation over the entire measurement domain. These challenges are overcome by careful design of the reference sites and their in situ measurements, which vary greatly depending on the geophysical parameter and on the footprint of the remote sensing product, and strategizing the utilization of diversity of validation sites with augmentation by other remote sensing products and models. Intersensor and inter-product calibration and validation are conducted to increase the length and fidelity of the time series or the coverage of the measurement. This is essential for utilization of remote sensing data for climate change studies.

Acknowledgments

This research was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the NASA.

CALIBRATION, MICROWAVE RADIOMETERS

Christopher Ruf

Department of Atmospheric, Oceanic and Space Sciences,
University of Michigan, Ann Arbor, MI, USA

Definition

Antenna temperature (T_a). A weighted average of the brightness temperature incident on a radiometer from all directions, where the weighting is the antenna radiation pattern.

Receiver noise temperature (T_{rec}). The equivalent brightness temperature that would produce the same signal strength as the noise generated by a radiometer's electronics.

System noise temperature (T_{sys}). The sum of the antenna temperature entering a radiometer plus its receiver noise temperature.

Antenna radiation pattern. The sensitivity of an antenna to incoming radiation, usually expressed as a function of angle of arrival in polar coordinates and normalized so that the integral over all angles is unity.

Antenna mainbeam. The portion of an antenna radiation pattern localized near the direction of maximum sensitivity.

Antenna sidelobes. The antenna radiation pattern away from its mainbeam.

Overview

A microwave radiometer measures the power associated with a particular polarization component of a propagating electromagnetic wave over a specific portion of the electromagnetic spectrum (see entry *Radiation, Electromagnetic*). The brightness temperature (T_b) in the direction from which the wave originated can be inferred from the power measurement. The T_b is specific to the polarization state and spectral range of the measurement. Raw radiometer power measurements generally contain contributions from other sources than the desired T_b , including incoming radiation from other directions and polarizations as well as radiation emitted by the radiometer receiver itself. Radiometer calibration consists of an accurate accounting for all significant contributions to the raw measurements and estimation of the desired T_b .

Antenna effects

In general, electromagnetic radiation incident on an antenna arrives from all directions and with all possible polarization states. An ideal antenna would selectively receive radiation with only the desired polarization and that arrives only from the desired direction. In practice, an antenna will receive radiation incident from all directions weighted by its radiation pattern. The weighted average of the incident T_b , weighted by the radiation pattern, is referred to as the antenna temperature (T_a). The mainbeam of the radiation pattern is the (typically narrow) range of directions over which the antenna is most sensitive. Calibrated T_b measurements by a radiometer are generally considered to originate from this range of directions. The sidelobes of the radiation pattern describe its sensitivity to radiation incident from all other directions outside the mainbeam. Typically 1–10% of the total power measured by a radiometer originates from sidelobe directions. Similarly, an antenna will receive radiation from all polarization states, weighted by its sensitivity to each component. An antenna's polarimetric gain matrix describes the sensitivity. Its main diagonal elements specify the sensitivity to the desired polarization, in a manner analogous to the mainbeam for directional sensitivity. The off-diagonal elements play a similar role as the antenna sidelobes, specifying the sensitivity to unwanted polarization states.

Calibration of a radiometer for antenna effects consists of correcting the T_a measurements for each of the unwanted contributors in order to estimate the T_b contribution with the desired polarization arriving from the mainbeam direction. Sidelobe corrections are generally made by (1) measuring or modeling the radiation pattern of the antenna; (2) estimating the mean T_b entering the antenna from its sidelobes; and then (3) subtracting the mean sidelobe T_b , weighted by the sidelobe sensitivity, from the raw measurements (Njoku et al., 1980). Similarly, polarimetric corrections first require that an antenna's gain matrix be known, usually by direct measurement in a specialized facility. If radiometric measurements are made of all polarization states of the incident radiation, then the gain matrix can be inverted mathematically to correct for the off-diagonal contamination (Gasiewski and Kunkee, 1993). If only some of the states are measured, then the others must be estimated prior to the matrix inversion.

Receiver effects

A radiometer antenna collects incident radiation and converts it to a voltage on a transmission line. A radiometer receiver amplifies that voltage to a more measurable signal strength, typically with transistor amplifiers, and then measures the time average of the square of the voltage. This measurement is directly proportional to the power in the signal. The measured power contains one component due to the antenna temperature and another due to thermal emission by the antenna and receiver. The latter

component is called the receiver noise temperature (T_{rec}), and the sum of the two is referred to as the system noise temperature (T_{sys}), that is, $T_{sys} = T_a + T_{rec}$. The raw power measurement made by a radiometer is equal to T_{sys} multiplied by the receiver gain. T_{rec} originates primarily from three sources. Both the antenna and the transmission line connecting it to the amplifier are typically made of a highly conducting metal. However, because the conductivity is finite, there will be a small resistive loss in power experienced by the signal as its current flows along the metal. The metal will reradiate its own thermal emission in order to remain in local thermodynamic equilibrium. This reradiation contributes to T_{rec} . The amplifier also generates its own emission, due in part to resistive losses at its input stage as well as other noise generation mechanisms within the transistor. Other noise sources are also present in the receiver after its first amplifier, but they have a relatively small effect on T_{rec} because the T_a portion of the signal has been significantly amplified at that point.

Calibration of receiver effects consists of estimating the receiver gain and T_{rec} and then subtracting T_{rec} from T_{sys} to obtain T_a . T_{rec} can be estimated in different ways, depending on the radiometer hardware architecture. Many radiometer antennas are mechanically scanned to sweep their mainbeam across a T_b scene and generate an image. In this case, it is common to place a pair of calibration targets with known T_b values at opposite edges of the scan (Hollinger et al., 1990). Their measurement allows for the determination of both the receiver gain and T_{rec} . Some radiometers are not mechanically scanned and it is impractical to place calibration targets in front of the antenna, especially in spaceborne deployments. In these cases, receiver gain can be estimated by intermittently adding a known noise source to T_{sys} and measuring the resulting change in power. To estimate T_{rec} , a calibration switch is often used, which redirects the input to the receiver from the antenna to a calibration target with a known T_b (Ruf and Warnock, 2007). This approach can be less accurate and stable because the calibration switch itself is a source of power loss and thermal noise and because the resistive losses in the antenna and the portion of the transmission line between it and the receiver are now outside of the calibrated portion of the receiver.

Conclusion

Calibration of a microwave radiometer is the process by which the T_b arriving from a particular direction at a particular polarization is estimated from its raw measurements. The raw measurements can be explained by considering the action of the radiometer antenna on the incident radiation and then considering the action of the radiometer receiver on the signal generated by the antenna. The principle instrumental effects that are corrected for by the calibration process are the sensitivity of the antenna to incident radiation from undesirable directions and at undesirable polarizations, the addition

of thermal emission to the measurement by the receiver itself, and the magnitude of the signal amplification by the receiver.

CALIBRATION, OPTICAL/INFRARED PASSIVE SENSORS

Carol Bruegge
 Jet Propulsion Laboratory, California Institute of
 Technology, Pasadena, CA, USA

Definition

Calibration. A set of operations that establish, under specified conditions, the relationship between values indicated by a measuring instrument and the corresponding known values of a standard. For remote sensors, this typically implies the radiometric, spectral, and geometric characterization of an instrument as needed to understand the impact of the instrument's performance on the data or the derived data products.

Calibration factors are determined by comparison with a standard whose output is known in accepted physical units as part of the *Système International d'Unités* (abbreviated SI). Units are based on the metric-kilogram-second (mks) system and include the Kelvin, for temperature, and Watt, for power. Derived radiometric parameters are listed in [Table 1](#).

The calibration parameters derived for a sensor must be reported with the associated uncertainty and confidence level. The uncertainty analysis needs to establish both the precision and absolute uncertainty. The *precision* of the calibration is the consistency with repeated measurements. The *absolute calibration* is determined by the sensor's response to stable standards. These should be related to international or national standards through an unbroken chain of comparisons.

Calibration, Optical/Infrared Passive Sensors, Table 1
Common radiometric parameters

Entity	Symbol	Units
Spectral irradiance (radiant flux density at a surface)	E_λ	$\text{W m}^{-2} \mu\text{m}^{-1}$
Spectral radiance	L_λ	$\text{W m}^{-2} \text{sr}^{-1} \mu\text{m}^{-1}$
Spectral reflectance (reflected flux/incident flux)	ρ_λ	Unitless

The *confidence level* is an interval about the result of a measurement within which the true value is expected to lie, as determined from an uncertainty analysis with a specified probability. A 3σ (sigma) confidence level implies that the stated uncertainty is achieved with 99 % probability.

Introduction

During the sensor development phase, the science and engineering teams first agree to set calibration requirements and a calibration approach. Absolute calibration requirements of 3–5 % (1σ) uncertainty are considered state of the art. Higher accuracy is typically specified for channel-relative or pixel-relative measurements. The accuracy is limited due to instrument-specific attributes, such as stray-light, out-of-field response, polarization sensitivity, scan-mirror sensitivity, linearity, signal-to-noise, temperature sensitivity, dark offset, and long-term stability. Radiometric uncertainty is increased when these effects alter the imagery and recorded signals in unpredictable ways.

Testing is conducted throughout the lifetime of the sensor. Characterizations of the filter and detector components provide early assurance that design requirements will be met. Preflight testing at the instrument level, before assembly onto the spacecraft, allows many parameters to be determined, which cannot be established on-orbit. This testing period is crucial to understanding the as-built performance. Following this, the program must commit to an on-orbit calibration plan. This allows response degradation, due to the browning of the optical elements or throughput change due to radiation damage, to be monitored. An adequate on-orbit calibration program will allow accurate radiance products to be reported even in the presence of sensor degradation. Both preflight and on-orbit calibrations are essential. An overview of the preflight testing for the Multi-angle Imaging SpectroRadiometer (MISR) is given by Bruegge et al. (2002).

Spectral response function

Most remote sensing systems measure incident light using several channels, where each channel is designed with a specified color sensitivity. That is, the instrument's per-channel output is designed to be a function of both the amount of incident light, as well as its wavelength. The color selection may be achieved by using spectral

filters within the instrument, or may be accomplished by use of a grating that disperses light according to the wavelength. In either case, the *spectral response function* (SRF) must be determined for each channel. This is a measure of the instrument's output as a function of the incident wavelength of light. The distribution only needs to be known in a relative sense, and is typically normalized to unity at the wavelength of peak response.

The SRF is measured using a test setup that can illuminate an instrument with monochromatic light, and where the wavelength of light can be varied during the test. The characterization should measure both the in-band response, near the region of peak sensitivity, and also the far-wing response. The hardware used is most commonly a monochromator. For instruments with very narrow spectral response functions, a tunable diode laser can be used, or Fourier Transform Interferometer (Strow et al., 2003). In either case, it is imperative that the system response be measured. It is insufficient to substitute the filter transmittance for this response, as all optical components, as well as the detector itself, contribute to the SRF.

It is common practice to summarize a sensor's spectral properties by tabulating the center wavelength and spectral width. This has been done by quoting the wavelength-of-peak response and full-width at half-maximum (FWHM). The latter is the wavelength at which the response falls to half of its peak value. These parameters can be misleading in cases where the SRF may be double peaked, asymmetric, or have a large out-of-band response. A better representation can be obtained from an equivalent square-band response analysis (Palmer, 1984). Here the sensor spectral response function is replaced with a function of equivalent area, but with an effective amplitude R_n and a throughput of 0 at wavelengths less than a computed minimum wavelength or greater than a computed maximum wavelength. Figure 1 gives an example of an SRF and square-band equivalent. The example is of Landsat-4, TM band 2 channel.

Radiometric calibration

Band-averaged radiances

Typically, raw data (digital numbers, or DN) from a sensor are converted to radiance units by knowledge of the gain coefficient. An example might be

$$DN - DN_0 = \bar{L}_\lambda \cdot G \quad (1)$$

where

DN is the sensor output count

DN_0 is the dark-scene output count

$\bar{L}_\lambda$ is the band-weighted spectral radiance incident onto the sensor ($\text{W m}^{-2} \text{sr}^{-1} \mu\text{m}^{-1}$)

and G is the radiometric response coefficient ($DN/[\text{W m}^{-2} \text{sr}^{-1} \mu\text{m}^{-1}]$)

Calibration, Optical/Infrared Passive Sensors, Figure 1 Spectral response function and moments-derived center wavelength and width for a typical detector.

A precise determination of the band-weighted radiance would require knowledge of both the spectral content of the incident light as well as the sensor spectral response function, R_λ . The band-weighted incident radiance is as follows:

$$\bar{L}_\lambda = \frac{\int L_\lambda R_\lambda \partial \lambda}{\int R_\lambda \partial \lambda} \quad (2)$$

For calibration, the gain, G , is computed with complete knowledge of the SRF and source spectral radiance. For radiance retrieval and science product generation, where output digital numbers are converted into radiances, the spectral content of the scene is not retrieved, rather only a band-weighted average.

Standards

The test equipment associated with a radiometric calibration requires an extended, spatially uniform, and spectrally smooth light source. A blackbody radiator is the most widely used source for infrared calibration. Its use in the visible, UV, and near-IR is limited. For these wavelengths, an integrating sphere or lamp and diffuse reflector fixture is more typical. The source must be larger than the geometric field of view of the sensor to be tested. This is to capture stray and diffracted light that will contribute to the output. Point sources of light are suitable for measuring a system's point spread function response, but are not suitable as radiometric targets.

If the source is an integrating sphere, its output needs to be calibrated by use of a transfer detector. The detector is, in turn, calibrated against a source standard. Standard

filament lamps are commercially available. The manufacturer typically seasons them by operating for 30 h. Lamps with output fluctuations are discarded. Suitable lamps are calibrated against a working standard that has a calibration traceable to national standards. These lamps can have accuracies approaching 1 % (2σ). Schneider and Goebel (1984) provide a review of standards.

On-orbit calibration

In-flight calibration is best accomplished using multiple technologies. Data from an on-board calibrator (OBC), for one, can provide the most frequent verification of sensor performance and stability. These systems can be used to make frequent checks on performance. Sampling dark current or the response to an attenuated view of the sun, for example, can be made once per orbit. As the OBC can itself degrade on-orbit, scene-viewing techniques are also required. Although considered the definitive validation of sensor performance, measurements are less frequent due to constraints associated with imagery collection. Scene studies can be as simple as observations of an un-instrumented desert site, or a highly accurate measurement of a site's in situ observations, and involving a field team or a network. Coastlines and contrasts edges can be used to confirm channel geolocation and co-registration. The SeaWiFS sensor makes use of lunar observations to track relative degradation changes (Eplee et al., 2001). Finally, cross-comparisons with sensors of similar footprints and bandpasses provide convincing error estimations. The comparison of radiances as determined from all techniques allows radiance uncertainty to be determined.

On-board calibrators

Examples of on-board calibrators can be found on EOS/Terra spacecraft sensors. The Multi-angle Imaging SpectroRadiometer (MISR) makes use of two deployable Spectralon diffuse targets. These are used to reflect sunlight into the earth-observing cameras. The panels have proven to be radiometrically stable on-orbit (Chrien et al., 2002). This is attributed to cleanliness and proper handling procedures that avoid exposure to contaminants (Stiegman et al., 1993). The panels are monitored by detector standards. Both radiation-resistant and high-quantum efficient detectors are utilized. The latter are intended to provide a measure of the incident light based upon physical principles, rather than transfer calibration using a standard source. In practice, detector stability has proven to be the driving criteria for detector selection.

The MODerate resolution Imaging SpectroRadiometer (MODIS), also on the Terra spacecraft, makes use of several on-board calibrator systems. These include a blackbody (BB) radiator, solar diffuser (SD), a solar-diffuse stability monitor, and the spectroradiometric calibration assembly (SRCA). The BB is the prime calibration source for the thermal bands located from 3.5 to 14.4 μm , while the SD provides a diffuse, solar-illuminated calibration source for the visible, near-infrared, and shortwave infrared bands ($0.4 \mu\text{m} \leq \lambda < 2.2 \mu\text{m}$). The SDSM tracks changes in the reflectance of the SD via reference to the sun so that potential instrument changes are not incorrectly attributed to changes in this calibration source. The SRCA is a very complex, multifunction calibration instrument that provides in-flight spectral, radiometric, and spatial calibration.

Unattended desert sites

The Sahara desert sites are considered stable with time. These sites have only small amounts of vegetation, are sparsely populated, and are typically found with clear-sky and low-aerosol conditions. Many instrument teams use these targets to monitor sensor degradation with time (Cosnefroy et al., 1996). Routine observations of sites such as Egypt_1 (26.10 East longitude, 27.12 North latitude) can be trended in order to determine the response degradation for a channel with time. Data are normalized by cosine of the solar zenith angle and the Earth–Sun distance. Observations are trended that are acquired at a fixed observation angle. This reduces error due to surface bidirectional reflectance factor (BRF) differences with view angle.

Vicarious calibration

Vicarious calibration (VC) is a process that is based upon in situ measurements acquired over a large, homogeneous desert site. With these data, the top-of-atmosphere spectral radiance can be computed and compared to those reported by the sensor as it simultaneously images the test site. Agreement constitutes

validation of the sensor's calibration. The in situ observations determine aerosol optical depths, surface spectral reflectance and BRF, and water vapor column amount. The top-of-atmosphere radiances are computed using a radiative transfer code such as MODTRAN. Vicarious calibrations can have uncertainties as small as 3 % (1σ). Key to the success of these measurements is the site selection. Western US desert sites, such as Railroad Valley, Nevada, are typically cloud-free and low in aerosols, minimizing errors in the radiative transfer calculation (Thome et al., 2003). It is for this reason that the vicarious calibration data is considered the radiometric standard for MISR, with the on-board calibrator adjusted to provide consistent calibrations (Bruegge et al., 2004).

Vicarious calibration requires visits by a field team to collect surface and atmospheric measurements at times necessarily coincident with a sensor over-flight. With the creation of an autonomous calibration facility, vicarious calibration data can be made available to the sensor community without the need for each research group to deploy its own field team. One example of an autonomous site is the LSpec (LED Spectrometer) automatic facility (Kerola et al., 2009). The facility is located at Frenchman Flat, within the Nevada Test Site. An array of eight LED spectrometers perform the autonomous function of recording surface reflectances at 5 min intervals, thereby permitting accurate and continual real-time scaling to a high-resolution characterization of the surface. Also resident at the LSpec site is a Cimel sun photometer, used to make atmospheric transmittance measurements. The Cimel is part of the Aerosol Robotic Network (AERONET; <http://aeronet.gsfc.nasa.gov/index.html>). Measurements made by the LSpec Cimel are used by AERONET to derive values of aerosol optical depths. From continuous in situ measurement of spectral reflectance of the playa surface, along with acquired aerosol optical depths and ozone optical depths (obtained from the Ozone Mapping Instrument OMI; <http://jwocky.nasa.gov>), the LSpec database provides all physical measurements needed to compute top-of-radiance with the same accuracy as traditional vicarious experiments. Data products are available to the public, and are available via a web-based interface at (<http://LSpec.Jpl.Nasa.Gov>).

Cross-calibration

The comparison of radiances from two or more sensors having similar passbands, acquired over a common target at near-coincident times can be a powerful validation exercise. In reality, the constraints on the measurements can be relaxed by making use of a radiance model for the site. That is, if the top-of-atmosphere spectral radiance can be determined, these data can be used to estimate the band-averaged radiance for a given sensor, at its SRF and for its time of observation. This is repeated for one or more sensors. The comparison of the first sensor

differenced to its model with the second sensor differenced to its model constitutes the cross-calibration (Thome et al., 2003).

Summary

There is an increasing demand for higher accuracy calibration. This is driven by the desire to have long-term data records that span multiple satellite programs. In an effort to establish best practices and minimize sensor-to-sensor biases, many international working groups and national standard laboratories are in collaboration. Information on the Committee on Earth Observation Satellites (CEOS) calibration/validation group can be obtained at <http://wgcv.ceos.org/>.

Acknowledgment

Imaging radar calibration

Definition

Synthetic aperture radar (SAR). A type of radar that forms high-resolution images of surfaces (planetary and terrestrial) using a technique known as aperture synthesis. *SAR calibration*. Encompasses all of the necessary steps taken to convert SAR image pixel values to fundamental units such as (normalized) radar cross section, measured in units of (m²/m²), or relative phase, measured in degrees. *SAR calibration performance*. An assessment of how well the calibrated SAR image pixel values correspond to the desired fundamental units.

Relative calibration performance (precision). An assessment of the relative errors between measurements made by a sensor of the same quantity separated in time or space. *Absolute calibration performance (accuracy)*. An assessment of the error in any single measurement made by a sensor as compared with an accepted, standard reference value.

Introduction

Synthetic aperture radar (SAR) was first conceived and demonstrated from aircraft in 1953 (Wiley, 1965). SARs are generally radars mounted on aircraft or satellite platforms and pointed sideways. The radar illuminates an area (referred to as its footprint) on the planet's surface down and off to the side of the platform track, and as the platform moves, this footprint traces out a swath that will eventually form the SAR image. SARs achieve high-resolution through aperture synthesis, a technique that combines radar returns collected from multiple (many) vantage points. This is done through signal processing, which generally occurs after the "raw" data has been sent down to the ground.

Early SARs were used to simply produce high-resolution images for military mapping purposes and later geologic or landform mapping. This was especially valuable in areas that were often cloud-covered and therefore unsuited to electro-optical sensor mapping. Interpretation and analysis of SAR images in this early period was not too different from photointerpretation of aerial photography and was therefore largely qualitative and highly subjective.

In the early 1980s, scientists using SAR data began to consider whether it could be used quantitatively, to allow geophysical quantities such as soil moisture, snow water equivalent, or surface topography (see also entry *Land Surface Topography*), for example, to be estimated directly from SAR measurements. Exciting results were being obtained from field experiments using well-calibrated, ground-based scatterometers with small footprints at around this time (Ulaby et al., 1982), and the expectation was that such local-scale results could be expanded to a global scale using SARs flown in space (Dubois et al., 1992). To achieve this, SAR data would have to be calibrated to standards similar to the ground-based scatterometers and to the same units, which had not happened up to that point. This challenge was vigorously tackled between 1987 and 1994 by scientists and engineers engaged in the field (Freeman, 1992).

As a result of all this effort, the first systematically calibrated SAR data became available to the science community in the late 1980s (van Zyl et al., 1992) from the NASA/JPL airborne SAR system (AIRSAR). This was followed in the early 1990s by calibrated data from the European Space Agency's ERS-1 spaceborne SAR (Attema and Francis, 1991), the Japanese Space Agency's JERS-1 SAR (Shimada, 1993), and NASA/JPL's SIR-C system in 1994 (Freeman et al., 1995). Since that time, calibrated SAR data has been the accepted norm, and systems such as the Canadian Space Agency's Radarsat or the Japanese Space Agency's PalSAR routinely deliver high-quality, calibrated SAR data to a broad science community.

External SAR calibration

During the 1980s, several groups around the world conducted experiments designed to calibrate SAR data collected over a given site. Examples include some of the field campaigns in support of the SIR-A (1981) and SIR-B (1984) missions, which carried a SAR in the payload bay of the space shuttle. Data from the SIR-A and SIR-B missions was largely uncalibrated, except for a few sites where calibration targets of known radar cross section were deployed and later used to estimate the radar cross section across the image (Way and Smith, 1991; Curlander and McDonough, 1991). This is referred to as external calibration. Calibration targets typically used in such experiments include trihedral corner reflectors, which resemble upturned pyramids in appearance and have a well-determined radar cross section, and

transponders, which can be tuned to have a range of radar cross sections and characteristics (Freeman et al., 1990).

Valuable as these field experiments were, it is of course impractical to deploy corner reflectors in every scene where one wants calibrated SAR data. Consider also that plans were under way in the 1980s to obtain high-resolution radar measurements of the surface of Venus and Titan by flying SARs on the Magellan and Cassini missions. What was needed was an approach that would allow systematic calibration of all data generated by a SAR sensor, without the need for calibration targets within the scene.

Internal SAR calibration

In the late 1980s, engineers began to adapt internal calibration methods developed for scatterometers (Ulaby et al., 1982), to allow the systematic conversion of all SAR image pixel values to fundamental units such as radar cross section. Internal calibration involved first constructing an error budget for the system that identifies all possible calibration error sources and their likely magnitudes. The next step is to design and build a radar system that is as stable as possible. All elements of the radar system that contribute to the calibration error budget and could therefore affect the final calibration performance are first characterized on the ground. Examples include the RF power measured in watts, which is transmitted by the radar when it illuminates the ground, and the gain of the receiver used to collect the reflected echoes from the area illuminated by the antenna footprint. SAR systems are somewhat unique in that the processing that turns the "raw" signal data collected by the SAR into high-resolution image data can also affect the calibration, so this therefore has to be factored into the error budget and characterized (Freeman and Curlander, 1989).

Preflight characterization of the individual elements of the SAR system is used to verify the system error budget. During flight operations, test signals are injected at reasonable intervals to check that the performance of the radar system is consistent with this preflight characterization. Examples of test signals are sinusoids or Gaussian noise sources covering a given RF frequency range, which are fed into the receiver. The RF power transmitted by the radar is also measured frequently. Some systems include capabilities to actively monitor the radar antenna performance (gain and pointing).

Putting all this together, systematic calibration of SAR data involves using the characterization of the end-to-end radar system from preflight and in-flight measurements, to arrive at a formula to convert the SAR image pixel values into fundamental units. The system error budget is then used to estimate the calibration performance for the final product. This calibration performance is verified using external calibration over sites containing calibration targets, or natural surfaces with sufficiently well-known radar reflectivity, such as the Amazon rain forest, or vegetation-free surfaces such as bare soil or open ocean.

Polarimetric SAR

One of the most challenging types of SAR data to calibrate comes from polarimetric radars, in which SAR images are collected simultaneously at several different polarizations. A typical polarimetric SAR system, such as NASA/JPL's AIRSAR, collects polarimetric SAR data by first transmitting a horizontally polarized radar waveform, then measuring the reflected energy from the surface in both horizontal (H) and vertical (V) polarizations. This produces radar images in what is termed HH and HV polarizations (H-transmit, H-receive and H-transmit, V-receive). The radar also transmits a vertically polarized waveform to produce images in VV and VH polarizations. H and V polarizations are orthogonal, and if one collects radar reflectivities in all four polarizations in this basis (i.e., HH, HV, VH, VV), then it is possible to synthesize what one would have seen with a radar configured with circular polarizations, for example (Zebker et al., 1987).

Polarimetric SAR data, besides allowing such polarization synthesis, are incredibly rich in information, and researchers have mined such data to retrieve estimates of soil moisture (Dubois et al., 1995), vegetation biomass (Dobson et al., 1992), and to differentiate between agricultural crops (Freeman et al., 1994). Polarimetric SAR data, when well-calibrated, can also be used to bound the underlying physics of the radar wave's interaction with the surface (Freeman and Durden, 1998) and to estimate structural characteristics (e.g., roughness scales) and electrical properties (dielectric constant or conductivity) of the surface under investigation (Oh et al., 1992).

Calibration of polarimetric SAR has its own particular set of challenges, one of which is that it is impossible to build a radar antenna that transmits or receives pure H or V polarizations. There is always some small contribution from the orthogonal polarization, termed cross talk, which has to be corrected or accounted for. van Zyl, (1990) was the first to derive a polarimetric calibration algorithm that used characteristics of naturally occurring surfaces to successfully correct for system cross talk. Another challenge is that the relative phase between polarizations (e.g., HH versus VV) contains significant information. Thus, approaches have been developed to calibrate relative phase between measurements (Sheen et al., 1989). Finally, interactions of the radar waveform with the ionosphere, particularly the effect of Faraday rotation (which changes the polarization of the radar waveform), are a significant source of calibration error at some wavelengths. Techniques to calibrate SAR data subject to Faraday rotation and at the same time other system effects appeared in the literature in 2004 (Freeman, 2004) and have since been validated using PalSAR data (Nicoll et al., 2007). Recently, interest has surfaced in a novel form of dual-polarized measurements known as compact or hybrid polarimetry, which carries less information than fully polarimetric SAR but has some advantages in terms of system design. Calibration of compact polarimetry systems presents some interesting challenges (Freeman et al., 2008).

Interferometric SAR

Interferometric SAR systems collect data from two different vantage points, and the relative phase between the two measurements is compared to estimate surface elevations or surface motion. Comparison of the relative phase between measurements allows observation of very subtle surface variations of the order of a fraction of the radar wavelength. Calibration of interferometric SAR then requires excellent phase calibration between measurements. These measurements may be made at the same time or over a time separation of years, in what is known as repeat-pass observations. This latter requirement introduces a long-term phase stability requirement into the system design.

Calibration of topography data derived from interferometric SAR data generated by the spaceborne radar topography mission (SRTM) was achieved by Rodriguez et al. (2006). Calibration of interferometric SAR data from different time periods was first demonstrated using ERS-1 data and has been demonstrated on a number of SAR missions since then. The largest calibration uncertainty in such repeat-pass observations stems from uncertainties in the relative location of the vantage points for each observation. The vector joining these two points is known as the interferometric baseline for that pair of observations. This baseline can vary from pass to pass, depending on the orbital characteristics of the platform and the degree to which the flight track can be controlled.

In recent years, techniques combining polarimetric and interferometric SAR have received a lot of attention (e.g., Dubois-Fernandez et al., 2005), with scientists publishing estimates of forest height derived from such data (termed PoLinSAR), using algorithms such as the random volume over ground model (Treuhaf et al., 1996). These techniques open up a new set of challenges for SAR calibration.

Conclusion

Since the late 1980s, calibrated SAR data has become the norm rather than the exception. Scientist using SAR data now expect it to be calibrated and to within known calibration uncertainties. Challenges exist in the calibration of SAR data from longer wavelength systems, subject to ionospheric effects, and when polarimetry and interferometry are combined. New science applications tend to push for better calibration performance, which also presents a challenge for the calibration engineer.

Acknowledgments

This research was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the NASA.

Definitions

Radar scatterometer. A calibrated radar designed to measure the radar backscatter cross section of a target, which is generally an area on the earth's surface.

Wind scatterometer. A scatterometer designed to measure the ocean's surface backscatter at multiple azimuth angles in order to estimate the near-surface vector wind. It is also used for ice melt/freeze, soil moisture, and vegetation remote sensing.

Normalized radar cross section. Area-normalized radar backscatter, which is the ratio of the incident and reflected radar signal power. Equivalent to the radar albedo. Often represented by σ^0 or sigma-o.

Geophysical model function (GMF). An empirical or analytic relationship between radar backscatter and geophysical quantity, that is, sigma-o is a function of the vector wind, polarization, and other parameters,

$$\sigma^0 = F(S, \chi, p, \dots)$$

where S is the neutral-stability wind speed (typically at 10 m height), χ is the relative angle between the radar illumination angle and the wind direction, p is the polarization (h or v), and $\dots$ represents other parameters such as the wave field, temperature, salinity, etc.

Introduction

A scatterometer is a carefully calibrated radar designed to measure the radar backscatter cross section (usually as the normalized radar backscatter coefficient) of a target, which is frequently part of a natural scene. Accurate calibration of the scatterometer-measured backscatter is critical to the utility of the scatterometer data, and much effort is expended to insure precise calibration of the radar. Scatterometer backscatter measurements are generally

used to infer geophysical properties about the target scene, for example, the near-surface wind speed, soil-moisture, or snow wetness. This is typically done with the aid of a geophysical model function (GMF) or functional relation that relates the parameter of interest to the radar backscatter. Thus, scatterometer calibration can also refer to the determination of this model function and the verification of the geophysical estimation from the scatterometer backscatter measurements. Note that radar parameters and the geometry used to collect the backscatter measurements must be accounted for in the GMF and that uncertainties in these parameters lead to errors in parameter estimation.

Scatterometer calibration fundamentals

Microwave scatterometers operate by transmitting a microwave signal toward the target and measuring the reflected or backscattered power; the radar cross section is computed from the backscattered power measurement. Due to thermal noise in the radar receiver and Rayleigh fading, the signal power measurement is corrupted by noise. A separate measurement of the receive-only noise power is made and subtracted from the signal-plus-noise measurement to estimate the signal power measurement. The signal-to-noise ratio (SNR) may vary from very low (less than -20 dB) to high (20 dB or more).

For areal (scene) targets, the backscattered signal power is related to the normalized radar cross section (σ^0) via the radar equation (Ulaby et al., 1981), which can be written as

$$\sigma^0 = P_s X \quad (1)$$

where P_s is the received backscatter power, and the backscatter conversion factor X (in simplified form) is

$$X = g P_t G^2 \lambda^2 A_c / (4\pi)^3 R^4 L \quad (2)$$

where processor g is a calibration correction, P_t is the transmitted power, G is antenna gain, λ is the wavelength of the transmitted microwave signal, A_c is the illuminated footprint area, R is the slant range to the surface, and L represents system losses, including processing losses. A key goal in scatterometer calibration is ensuring accurate computation of the backscatter cross section by selecting appropriate values for g and X .

More accurate expressions for X include an integral of the radar equation parameters over the surface, for example,

$$X = \frac{P_t \lambda}{(4\pi)^3 L} \iint g(x, y) G(x, y) / R^4(x, y) dx dy \quad (3)$$

where the integral is defined over the non-negligible antenna gain and x and y are orthogonal surface coordinates. (Other forms may be more convenient for a given application such as expressing the integral in terms of antenna angles.)

The parameters in X can be split into two categories: those that depend on the observation geometry (G , A_c , R , and possible contributions to g and L) and those that depend on the radar design and RF system gain (P_t , λ , and possible contributions to g and L). Thus, scatterometer backscatter calibration requires both geometric and radar parameter procedures. The parameters g and L include factors such as signal spill-over and clipping loss from the radar range gates, signal processing filters, the processing scheme employed, etc. These parameters are highly instrument-specific; techniques for determining them must be adapted for each sensor.

Backscatter calibration

The scatterometer backscattered signal from the target scene consists of distance-attenuated, time-delayed, frequency-shifted copies of the transmitted signal. The time delay arises due to finite speed of light and the distance (sometimes referred to as the slant range) between the radar and the scene. Variations in the time delay due to spacecraft pointing, topography, and orbit can result in signal power loss by the range gate. The relative motion of the radar with respect to the scene introduces Doppler frequency shift, and variations in Doppler can introduce power variations due to nonideal filters. These must be accounted for in computing X . Uncertainties or errors in computing X affect both the mean and variance of the σ^0 measurement. Scatterometer σ^0 measurement calibration includes insuring that both the mean and variance in the estimated σ^0 error in the measurement are minimized. This is complicated by measurement errors due to radiometric noise and Rayleigh fading, which results from time-fluctuation of the self-interference in the echo signal (Ulaby et al., 1981, 1990).

A model for the measured backscatter σ_m^0 observed by the scatterometer is

$$\sigma_m^0 = \sigma^0 (1 + K_p v) \quad (4)$$

where σ^0 is the true or expected backscatter of the surface, K_p is the normalized standard deviation (sometimes referred to as the radiometric accuracy) of the measurement error, and v is typically a normally distributed Gaussian random variable. The multiplicative noise model in Eq. 4 arises, in part, as a result of speckle noise, an inherent limitation in coherent radars. The measurement variability K_p can be expressed as (see also Yoho and Long, 2003, 2004)

$$K_p^2 = K_{pc}^2 + K_{pr}^2 + K_{pm}^2 \quad (5)$$

where K_{pc} is the “communications” variability due to radiometric noise, K_{pr} is the calibration uncertainty and variability, and K_{pm} is the modeling variability. A key goal in scatterometer calibration is to minimize K_{pr} and K_{pm} . K_{pc} can be written as a quadratic function of the true signal-to-noise ratio ($\text{SNR} = P_s/P_n$ where $P_s = X_t \sigma^0$ is

the signal power, X_t the true value of X , and P_n is the noise power),

$$K_p^2 = \alpha + \beta/\text{SNR} + \gamma/\text{SNR}^2 \quad (6)$$

where α , β , and γ depend on the radar hardware and the signal processing used (e.g., Fischer, 1972; Long and Mendel, 1991; Naderi et al., 1991; Yoho and Long, 2003, 2004).

Accurate ground-based calibration of the RF hardware is required to compute amplifier and antenna gains, filter responses, timing, and other parameters affecting X and the K_p parameters α , β , and γ . Scatterometers employ carefully designed and calibrated signal feedback paths that attenuate the transmit signal and feed it into the receiver. This permits monitoring and frequent internal calibration of the end-to-end RF system gain. Separate calibration and characterization of the antenna gain pattern must be performed prelaunch.

Once on-orbit, the total system gain including the antennas can be verified by using ground calibration stations. Receive-only, receive/transmit, and transponder ground stations have been used. Transponder stations receive the signal, amplify it by a fixed amount, (optionally) frequency-shift it, and retransmit it toward the orbiting instrument. This provides a signal that stands out against the ordinary backscatter in the measurement data, which enables the system signal timing and ground station received power to be checked against predicted values. As the sensor flies overhead, data from a fixed ground station provides a “slice” through the antenna pattern and measurement swath. Multiple stations enable multiple simultaneous slices to verify and calibrate antenna gain along fan-beam antenna patterns. Typically, ground stations use broad-beam horn antennas that are steered toward the scatterometer as it flies overhead in order to minimize possible signal gain variations in the ground station antennas. With care, absolute system calibration can be accomplished. However, while ground stations are effective in verifying calibration and providing on-orbit adjustments to antenna patterns, achieving the desired high-precision absolute system calibration (better than 0.1 dB) can be difficult since the calibration precision of the ground station is difficult to achieve and maintain.

A widely used alternate approach to system calibration is the use of natural targets. These regions have been used as calibration transfer standards to ensure accurate cross-calibration of multiple instruments. Distributed area targets that have a spatially uniform, temporally stable backscatter response are desired. Rain forests have been widely used for scatterometer calibration due to their wide areal extent and low seasonal variation, but other regions have also been used, including firm at the summits of Greenland and Antarctica and (during certain seasons) deserts and Asiatic steppes. The absolute backscatter of these regions is not known precisely, so natural scenes are generally used for relative calibration of the

backscatter versus observation geometry (such as azimuth angle or intra-footprint) over the scatterometer measurement swath. Rain forests have proven to be the most effective in intersensor calibration and as transfer standards in cross-calibrating difference sensors. Such areas are useful for long-term monitoring of sensor drift.

In the case of dense vegetation, the radar cross section is primarily dependent on the canopy density and varies nearly linearly (in dB) with measurement incidence angle. Carefully selecting homogenous areas within the rain forests that have minimal seasonal variations provides constant regions with the desired calibration characteristics. While the Amazon and Congo rainforests have been widely used, the rainforests of Borneo have proven less suitable for scatterometer calibration due to the mountainous terrain. Seasonal and daily variations in canopy moisture content, particularly daily cycles of dew, introduce some variability in the forest backscatter. For a fixed time of day, the areal average backscatter variation is estimated to be ± 0.15 dB at both Ku- and C-band (Long and Skouson, 1995; Long, 1998). Excluding measurements made in areas with recent (within 24–48 h) rain reduces the variability. Considerations for incidence and azimuth angle variations are essential, particularly in deserts and snow-covered areas, due to the presence of dunes that exhibit strong azimuthally dependent scattering characteristics.

We note that because of its narrow footprint, pencil-beam scatterometers such as SeaWinds on QuikSCAT receive-only measurements can function as radiometer observations useful for detecting rain. Calibrating QuikSCAT radiometric measurements requires converting the receive-only power measurements into brightness temperature values. Prelaunch RF calibration provides key receive system calibration parameters. Post-launch, comparisons of collocated brightness temperatures measured over extended area targets by conventional radiometers are used in order to complete the calibration process (Jones et al., 2000).

GMF calibration

Scatterometers are designed to accurately measure σ^0 in order to infer geophysical properties from the σ^0 measurements with the aid of a GMF that relates σ^0 with its observation geometry and the geophysical property of interest, for example, the near-surface ocean wind. An important component of scatterometer calibration is thus to ensure the accuracy of this indirect estimation process by “calibrating” the GMF. In this context, “calibration” refers to validating the accuracy of the estimated geophysical property, for example, the surface wind, by comparison to independent measurements, for example, from buoys. The GMF or backscatter calibration is adjusted to minimize the error (and variance) of the estimated geophysical parameter.

GMF calibration is conducted with the aid of campaigns to collect surface parameter data that is

compared to spatially and temporally collocated backscatter measurements. An extensive literature exists on this topic. Ideally, the surface measurements span the expected range of the parameter of interest and parameters that may affect it. For example, for wind calibration, buoy and/or ship measurements are collected at multiple locations with varying sea-surface temperature, wave conditions, and locations within the scatterometer swath. The comparison data is segmented in various ways in order to evaluate potential sensitivity to unmodeled factors, for example, sea-surface temperature or significant wave height. Near-surface wind measurements are controlled or adjusted to similar heights, fetch, and atmospheric stability conditions using bulk corrections. Assumptions of ergodicity are required comparing buoy point measurements to areal average scatterometer measurements. Rain and land proximity adversely affect the accuracy of scatterometer-derived wind estimates and so only open ocean and no-rain surface data are considered in wind GMF calibration. The size of the scatterometer footprint alters the distribution of the backscatter, particularly in low-wind conditions that can result in very low backscatter. At the other extreme, high winds can saturate the GMF, leading to reduced wind estimate accuracy.

An alternate GMF calibration approach relies on comparison of winds generated from numerical weather prediction (NWP) models and collocated scatterometer backscatter values. While all NWP models have accuracy limitations, the underlying assumption of the alternate approach is that if enough collocated backscatter measurements and NWP winds are collected, the NWP errors "average out," enabling estimation of an empirical GMF by binning the backscatter data according to the NWP output value. Though not without limitation, this technique has proven highly successful for scatterometer GMF calibration. GMFs, to support simultaneous wind and rain estimation from scatterometer backscatter measurements, rely on both NWP winds and collocated measurements from other sensors, such as radiometers or rain radars, to derive rain-effect and correction models.

Conclusion

Scatterometry has proven to be a very useful tool for operational wind measure and monitoring and studying the earth. Scatterometer data complements the data from other sensors in long-term studies. An essential element in the success of scatterometry is the precise calibration of the data, which accounts for the detail and attention scatterometer calibration is given.

CLIMATE DATA RECORDS

Eric F. Wood

Department of Civil and Environmental Engineering,
Princeton University, Princeton, NJ, USA

Definition

Following NRC (2004), a climate data record (CDR) is defined as *a time series of measurements of sufficient length, consistency, and continuity to determine climate variability and change*. For satellite-based CDR, these can be further defined as *fundamental CDRs (FCDRs)*, which are calibrated and quality-controlled sensor data that have been improved over time, and *thematic CDRs (TCDRs)*, which are geophysical variables derived from the FCDRs, such as [sea surface temperature](#) and cloud fraction.

Applying the nomenclature that a satellite record meets the standard of a CDR implies that the products were generated and maintained with attention to data stewardship and management, with developed access and dissemination policies. CDR often requires updating and reprocessing to maintain consistency and quality, which implies that the underlying datasets and information used in their creation, such as metadata, are preserved indefinitely in formats that promote easy access. Products deemed a CDR requires commitment for long-term data storage, access, and management.

Key elements of a climate data record activity

CDR organizational elements

1. An advisory and review team to provide input to development of a CDR (FCDR) from satellite data, to review the theoretical basis for the CDR (FCDR) algorithm, and to review the generated CDR (FCDR) products.
2. An advisory and review team for a fundamental CDR should have specific expertise for that product. For thematic CDRs (TCDRs), advisory and review teams should reflect broad disciplinary theme areas.

CDR generation elements

1. FCDRs must be generated with the highest possible accuracy and stability.
2. Sensors must be thoroughly characterized before and after launch, and their performance should be continuously monitored throughout their lifetime.

3. Sensors should be thoroughly calibrated, including nominal calibration of sensors in orbit, vicarious calibration with in situ data, and satellite-to-satellite cross-calibration.
4. TCDRs should be selected based on well-defined criteria established by the advisory and review team.
5. Validated TCDRs must have well-defined levels of uncertainty.
6. An ongoing program of correlative in situ measurements is required to validate TCDRs.

Sustaining CDR elements

1. Resources should be made available for reprocessing the CDRs as new information and improved algorithms are available, while also maintaining the forward processing of data in near real time.
2. Provisions should be included to receive feedback from the scientific community.
3. A long-term commitment of resources should be made to the generation and archival of CDRs and associated documentation and metadata.

CLIMATE MONITORING AND PREDICTION

Mathew R. P. Sapiano

University of Maryland - College Park, College Park,
MD, USA

Definition

Climate. Time average of atmospheric properties. The objective of the temporal averaging is to establish a background state of behavior that is the most likely state of the atmosphere at any given time. Weather variations are considered to be superimposed on the background climate, while at any given location the climate is viewed as changing through the year; thus, a location has a different climate state for each month of the year. Spatial averaging is generally used as well, but if sufficiently detailed observations are available, microclimates of any desired scale can be defined. Climate variability is the year-to-year change in climate at a given location and time of year; if temporal and/or spatial coherence can be identified in

these variations, coherent modes of climate variability such as the El Niño/Southern Oscillation (ENSO) or the North Atlantic Oscillation (NAO) may be described.

Climate monitoring. The practice of describing the current state of the climate system and the status of coherent aspects of climate variability, generally through the use of temporally averaged atmospheric observations.

Climate prediction. Prediction of the future state of the climate system on seasonal to interannual timescales, often distinguished from climate change projections on longer timescales. An overlap exists between these concepts on timescales of several years to several decades.

Introduction

Mark Twain provided the most succinct definition of climate by defining its relationship with weather: “Climate is what we expect, Weather is what we get.” Contrasting weather with climate is perhaps the best approach to defining climate. The weather we observe is deterministic and dynamical; there is a single realization of the weather that is/was actually observed, albeit subject to some measurement error. Climate, on the other hand, is inherently statistical and is often thought of as the *mean state of the weather*, where this mean can be either in time or space (and commonly both). Additionally, weather can be thought of as being deterministic and climate is probabilistic, in that it is the most likely outcome out of some range of possible values (note that the mean usually satisfies the criteria of being the most likely outcome). For example, we might know that it rained on some given day (although there is, of course, measurement error on such an estimate), but the climate estimate of whether it rained on any given day might be a probability of rain rather than an outright answer. For climate monitoring and prediction, the mean underlying state of the Earth system at some given timescale (say the seasonal scale) is of prime interest.

In practical terms, weather monitoring, climate monitoring, and climate change monitoring are often differentiated by the timescale of the signal of interest which is important as a control of the allowable noise/error levels in the data. Weather scales include high-frequency variations and are typically defined as being between zero and 10 days, with longer timescales being more typically associated with climate signals. Climate change signals are generally small and low frequency and are defined as occurring over multiple decades or centuries. Climate monitoring includes scales longer than a few days but still within the period of a few months or years and generally involves the averaging of multiple weather events. Examples of this might be an enhanced hurricane season, a prolonged drought, or even a more expansive hole in the ozone layer.

Despite the many engineering and technical challenges associated with remote sensing datasets, they play a vital role in climate monitoring. Before remote sensing,

observations were limited to single point locations which were generally made in well-populated areas. Remote sensing through radar and satellite observations provides far increased spatial coverage as well as enhanced temporal sampling. This has allowed exploration of the climate in areas of little or no knowledge as well as an understanding of the processes acting at sub-daily timescales. The latency (time until availability) of remotely sensed is also ideal for climate monitoring. Traditionally, climate monitoring products were compiled months after the fact, but remotely sensed data is often available in real time so that global monitoring datasets can be available in mere hours. The construction of climate monitoring datasets from radar networks provides a significant technical challenge and few exist (a notable exception is the Stage IV US gauge-corrected radar precipitation estimates; Lin and Mitchell, 2005). Satellite observations, however, have proven crucial in both climate monitoring and climate change studies and have filled significant gaps in our records most notably, the global oceans.

For the purposes of this entry, we characterize remotely sensed observations in four groups in order from the most direct to the least direct:

1. Direct measurements of climate parameters, specifically the radiation budget at the top of atmosphere
2. Inferred measurements of the current state of important climate characteristics, such as clouds, SST, vegetation, and moisture
3. Contributions to the definition of the initial state of the climate system for prediction or reanalysis models
4. Verification data to for the assessment of climate models and other products and their ability to predict characteristics of the climate system

These groupings are by no means mutually exclusive, with the third and fourth making considerable use of direct and inferred measurements of climate parameters from the first and second group.

We will give examples of the first three groups in the following sections; the fourth is neglected since this is not directly relevant to climate monitoring and prediction, although it is a necessary part of product development. The vast majority of climate monitoring is achieved using inferred observations which fall under the second group, so this section is the largest and has several examples. Remotely sensed data is used in a wide range of different monitoring and prediction capacities; thus, a full survey of all possible activities is impossible. Likewise, each monitoring or prediction product utilizes different techniques, sensors, and algorithms which are too varied to allow for simple classification.

Measurements of the radiation budget

Spaceborne remotely sensed observations directly measure emitted or reflected radiation at the top of the atmosphere (TOA). Thus, the most direct measurements available from satellites are of the radiation budget which

includes the surface albedo, reflected shortwave radiation from the Sun, and emitted long-wave radiation (usually from the Earth's surface or clouds). While the albedo is fixed for a given surface type, the latter two are modulated by the Earth system. The TOA radiation budget is known to be critically important for climate: Global climate change is a reaction to changes in the energy budget due to increased greenhouse gas concentrations in the atmosphere. Despite the importance of the radiation budget to the climate system, it is still not fully understood how short-term perturbations affect the climate, and, as such, radiation balance estimates are not directly used in climate monitoring. However, estimates of the radiation budget are used to assess the performance of climate models, and so these observations are directly used in that context.

Example 1: total solar irradiance

Estimates of incoming solar radiation were traditionally made through the proxy of sunspot counts (see [Radiation, Solar and Lunar](#)). Sunspots are magnetic disturbances on the Sun's surface that have lower temperatures than their surroundings and lead to slight variations in solar activity with a regular 11 year cycle. Total solar irradiance (TSI) is a more direct measurement of solar activity and is defined as the wavelength-integrated solar radiation received by a surface at an average distance from the Sun at the top of Earth's atmosphere. Measurements of TSI are not possible from Earth's surface due to the effects of the atmosphere on radiation and so measurement of TSI was only made possible with the advent of satellite observations. The historical record of TSI is comprised of several different radiometers aboard different missions (see Fröhlich and Lean, 2004 or Fröhlich, 2007, for details). Multiple combinations of these datasets are available, each with different calibrations (Fröhlich, 2007). The most recent sensor to be launched is the Total Irradiance Monitor aboard the Glory satellite (Mishchenko et al., 2007) which will continue the record of TSI measurements into the future.

TSI is an example of a parameter which is primarily monitored for climate change detection and attribution studies. The "standard" value of TSI is approximately $1,366 \text{ Wm}^{-2}$ although absolute calibration of sensors is extremely challenging and disagreement exists over the mean value. Over the course of the solar cycle, small variations occur of the order of 2 Wm^{-2} (de Toma et al., 2004; Rottman, 2006). Variations in TSI are known to affect climate, and there has been much debate as to whether trends in TSI (or other measures of solar activity such as spectral changes or changes in cosmic rays) could explain recent increases in global temperature. The IPCC AR4 Report (Forster et al., 2007) showed that the contribution of TSI is small and that it is not the main driver of observed changes, although TSI does account for some of the increase.

While TSI affects almost all climate parameters, its effects are greatly obscured by its indirect nature: Solar radiation is the primary driver of the Earth system but it

is modulated by that system. Daily data are routinely available from the web, such as data from the Solar Radiation and Climate Experiment (SoRCE), and can be used in conjunction with other data to understand major solar events such as solar flare activity (e.g., Woods et al., 2004) which impact the Earth. Despite the direct link with the Earth system, it is unclear as to whether TSI variations are large enough to affect the Earth system in a medium-range sense and how to interpret and use these observations for climate monitoring.

Measurements of climate parameters

Estimates of Earth system parameters derived from satellites are based on inferences made from measurements of TOA radiation in different channels. The exact nature of these inferred measurements is different for each parameter, mission, sensor, and orbit type. Many parameters require the use of several channels to derive a more accurate estimate, and multiple satellites are often used. For instance, precipitation estimates usually use a mixture of geostationary infrared and polar-orbiting passive microwave estimates to achieve the best global estimate. Multisatellite estimates are commonly used in climate monitoring since these are often superior for surface parameters. The following examples are arranged in order from TOA to the surface and are not intended to be exhaustive, but it is hoped that they are sufficient to provide the interested reader with a foundation for further reading.

Example 2: ozone

In the latter part of the twentieth century, before the concept of global climate change had entered the public psyche, there was great public alarm over the discovery of a decline in [stratospheric ozone](#) and the existence of a hole above Antarctica in the thin ozone layer (see [Stratospheric Ozone](#)). Ozone is a gas residing primarily in the stable part of the atmosphere above the turbulent troposphere called the stratosphere. Stratospheric ozone occurs naturally at 15–35 km above Earth's surface where ultraviolet (UV) radiation from the Sun fuels a constant cycle of creation and destruction which keeps ozone levels in equilibrium. The ozone layer therefore absorbs nearly all UV radiation which can be harmful to human life, leading to a range of issues including forms of skin cancer. It was discovered in the 1970s that some man-made substances including chlorofluorocarbons (CFCs) were reaching the stable stratosphere and destroying ozone faster than it could be replenished. The Montreal Protocol was established in 1987 (and amended several times since) with the aim of phasing out the use of certain man-made chemicals known to destroy ozone. The treaty has been widely hailed as a success, and global stratospheric ozone levels have begun to recover, although the seasonal Antarctic ozone hole continues to exist and is not expected to recover to pre-1980 levels until midway through the twenty-first century (WMO, 2007).

This ongoing environmental issue is an example of how climate monitoring can have a major impact on society. In situ observations were made throughout the twentieth century, but the emergence of satellite observations with near-global coverage gave the data required to force policy makers into action. The Solar Backscatter Ultraviolet instrument (SBUV/2) aboard the NOAA series of satellites measures scattered UV rays to produce estimates of the total ozone as well as the vertical profile (Bhartia et al., 1996). The European Space Agency (ESA) Global Ozone Monitoring Experiment (GOME) instrument also provides total column ozone and the ozone vertical profile (Burrows et al., 1999) based on backscattered UV radiation.

The United Nations Environment Programme (UNEP) Ozone Secretariat is the primary international body for ozone monitoring. They have produced several assessment documents including the *Scientific Assessment of Ozone Depletion* series of reports which form the basis of global ozone monitoring. Other agencies such as the NOAA Climate Prediction Center (CPC) and other country-level meteorological agencies monitor the current state of stratospheric ozone.

Ozone is also found in much lower concentrations at low levels from anthropogenic sources. This so-called tropospheric ozone is regarded as a pollutant and can lead to serious, direct human health repercussions such as respiratory problems. The mechanisms leading to the formation of tropospheric ozone are different to those of stratospheric ozone, but similar techniques can be employed to retrieve estimates from remotely sensed information. While these estimates are not used in a climate monitoring sense, they are used in air quality forecasting.

Example 3: precipitation

Accurate measurements of precipitation are challenging because of the high variability of rainfall in both time and space (see [Rainfall](#)). Significant individual rainfall events can be as short as a few minutes in the case of highly localized convection or last several hours or days and be spread over a large area, as is the case for large-scale stratiform events. Differences in the relative skill of these precipitation estimates are frequently related to the ability to continuously sample precipitation so as not to miss short or small events. For that reason, gauges are usually considered the best source of precipitation data since they provide a time-integrated observation and have few calibration errors. However, gauges can be biased by wind-induced under-catch or other external factors, and coverage is often limited to populated areas where observers can access them. Ground radar estimates give good sampling over a limited area, but calibration issues preclude their combination to form a truly global dataset (the Stage IV radar dataset is a notable exception for the United States only). Satellite estimates of precipitation have larger sampling errors than either gauges or ground radar estimates but give the only estimates over the ocean. Satellite precipitation estimates are based on either

polar-orbiting passive microwave (PMW) or geosynchronous infrared (IR), where the more direct methods of the former generally give superior estimates. Additionally, the NASA Tropical Rainfall Monitoring Mission (TRMM; Kummerow et al., 1998) Precipitation Radar (Iguchi et al., 2000) also provides precipitation estimates, but these are limited to the tropics and the temporal sampling is insufficient for climate monitoring or prediction at the present time.

Despite the advantage of global coverage, satellite-only precipitation estimates are generally considered inferior to combinations of gauge data. Therefore, the most widely used precipitation datasets are combinations of multiple types of data. The two most commonly used precipitation datasets are the Global Precipitation Climatology Project (GPCP; Huffman et al., 1997; Adler et al., 2003) and the CPC Merged Analysis of Precipitation (CMAP; Xie and Arkin, 1997). Both datasets are global, monthly, 2.5° combinations of IR, PMW, and gauge data and a single month of GPCP is shown in [Figure 1](#). A significant barrier to the use of these datasets for real-time monitoring is that the gauge components are not immediately available. The suite of GPCP outputs therefore includes a provisional product which contains most of the combined satellite data and a slightly different, less comprehensive gauge analysis which is available in near real time, but with slightly reduced accuracy which is suitable for climate monitoring. As well as use for the general monitoring of precipitation, these large-scale estimates can also be used in derived products as a key predictor. One particularly useful application is in public health where precipitation has been used for disease risk mapping through disease vector prediction (e.g., Lobitz et al., 2000).

Before the launch of the TRMM mission, there were insufficient polar-orbiting PMW satellites to provide better than daily temporal resolution, but this sampling has been greatly improved with the addition of TRMM (which includes the TRMM Microwave Imager) along with several other PMW instruments such as the Advanced Microwave Sounding Unit (AMSU; Weng et al., 2003) and the Advanced Microwave Scanning Radiometer (AMSR; Wilheit et al., 2003). Several datasets have merged the available PMW estimates with the lower quality but more frequently sampled IR data. These datasets have near-global coverage with resolutions as fine as 8 km every half hour (CMORPH; Joyce et al., 2004) and can include gauge data through a monthly bias correction (TRMM Multi-satellite Precipitation Analysis; TMPA; Huffman et al., 2007). These high-resolution precipitation products are used in a number of climate monitoring situations for near-term predictions such as flash flood prediction (Gupta et al., 2002; Harris et al., 2007) and landslide prediction (Hong et al., 2006, 2007).

Example 4: vegetation

The most commonly used remotely sensed vegetation product is the normalized difference vegetation index

Climate Monitoring and Prediction, Figure 1 GPCP V2 mean precipitation for April 2008, in mm day^{-1} .

(NDVI; Tucker, 1979) (see Vegetation). NDVI is based on near-infrared (NIR) and Red channels and is simply defined as $(\text{NIR} - \text{Red}) / (\text{NIR} + \text{Red})$ which is normalized to range from -1 to 1 . NDVI is well correlated with the health of vegetation and is based on how green the vegetation is within each observed pixel. Most surfaces equally absorb or reflect in the Vis and NIR channels and give a near zero value of NDVI. Chlorophyll, however, absorbs in the Vis channel while leaves reflect in the NIR channel so that large differences usually denote healthier (or more green) vegetation within a pixel. The most commonly used instrument for the estimation of NDVI has been the Advanced Very High resolution Radiometer (AVHRR) which has flown aboard several missions and continues to provide high-resolution data with near-global coverage. NDVI estimates are used in agricultural and drought monitoring where the health of the crops and vegetation is the primary monitoring target. An important attribute of satellite remote sensing is that observations transcend traditional international boundaries. This is an important characteristic for drought and crop monitoring, as NDVI products can be used to observe countries where ground observations are not available, but where food aid might be required. Derived products are also available, and systems have been developed which forecast disease outbreaks based on NDVI and other variables (Linthicum et al., 1999; Hendrickx et al., 2001; Anyamba et al., 2002).

In general, these studies are based on the use of NDVI and the health of plants as a proxy for the health of disease vectors.

Example 5: sea ice

Observations of sea ice extent and concentration are required for both climate change studies and seasonal monitoring (see [Sea Ice Concentration and Extent](#)). The cryosphere is known to be particularly sensitive to changes in global temperature, and the signs of climate change have been most visible in the diminishing Arctic sea ice and the alarming and spectacular breakup of Antarctic ice sheets. However, sea ice also plays an important role in several other climate monitoring datasets, and monitoring products are commonly used in a range of other remotely sensed products to screen out areas where retrievals are either not possible or require modification. Sea ice extent is estimated using a number of different techniques based on passive microwave and infrared observations as well as some limited in situ observations. The NOAA/NESDIS Interactive Multisensor Snow and Ice Mapping System (IMS; Helfrich et al., 2007) is a commonly used merged satellite sea-ice extent product. A single day of the IMS snow (white) and ice (light gray) product is shown in [Figure 2](#). Snow and ice cover are determined by a human forecaster based on remotely sensed data from all sources. Such products are useful

IMS 24km 15 April 2008

Climate Monitoring and Prediction, Figure 2 IMS Northern Hemisphere snow and ice cover (at 24 km resolution) for 15th April 2008.

for precipitation products where retrievals are often not possible in the presence of snow/ice and ice masks are sometimes used to remove erroneous values. Analyses of sea-surface temperature (SST), such as the Reynolds and Smith (1994) analysis discussed later on, use sea ice products to infer temperature over ice-covered surfaces.

As well as ice extent (or snow cover), the concentration or thickness of ice is of interest, as is the age of the ice (whether the ice is new or has existed for multiple years). Sea ice concentration can be inferred from the Quick Scatterometer (QuikSCAT), the Special Sensor Microwave/Imager (SSM/I), the Scanning Multichannel Microwave Radiometer (SMMR), and, more recently, the Advanced Microwave Scanning Radiometer (AMSR). Such measurements are critically important for climate change monitoring such as the estimation of the depletion of sea ice (e.g., Nghiem et al., 2006). More recently, the Gravity Recovery and Climate Experiment (GRACE) has been used to estimate ice sheet mass inferred from measurements of Earth's gravity.

Example 6: sea surface temperature

Estimates of [sea surface temperature](#) (SST) are used in both a climate change monitoring and a seasonal climate monitoring capacity (see [Sea Surface Temperature](#)). For climate change, estimates of SST are important as an indicator of observed changes but also for understanding the global response to carbon dioxide. In a monitoring sense, global SST estimates serve a wide range of functions.

One of the most important indicators of global climate is the El Niño/Southern Oscillation (ENSO) which is chiefly associated with changes in the location and extent of the Tropical-Pacific warm pool and is hence often defined as an average of sea surface temperatures. ENSO variability is associated with a broad range of global weather phenomena and is a dominant component of many climate predictions (further discussion appears later in this section). SST is also an important consideration in hurricane monitoring and prediction since warmer SSTs are required for the initiation of convection and are thus a key component for predicting areas where strengthening of tropical storms is more likely. One of the most widely used gridded SST analyses is the Reynolds and Smith (1994) optimal interpolation (OI; also known as Kriging) of available ship observations and satellite estimates. A single month of this SST estimate is shown in [Figure 3](#). The original dataset used only estimates from the five-channel Advanced Very High Resolution Radiometer (AVHRR) instrument which became operational aboard NOAA-7 in 1981, although it has been updated in successive years. As with many other parameters, merged IR/PMW estimates of SST are quickly becoming the standard and allow for superior estimates. One such dataset is the high-resolution version of the Reynolds and Smith (1994) SSTs which is available at 0.25° daily resolution and uses remotely sensed data from the pathfinder AVHRR from 1981 onward and a mix of AVHRR and Advanced Microwave Scanning Radiometer (AMSR) after its launch in 2002 (Reynolds et al., 2007). SST data have been directly or indirectly used for a variety of monitoring purposes including monitoring of the thermohaline circulation (Latif et al., 2004), as an input for malaria prediction models (Thomson et al., 2005) and as an input for models of coral bleaching (Maynard et al., 2008).

Climate prediction and reanalysis

Remotely sensed observations have become an important input to numerical weather and climate models as a main constituent of the analysis of the initial conditions. Numerical forecasts work by propagating a set of initial conditions according to the theoretical physics of the system. The process of estimating the initial condition is called *data assimilation* and involves collecting all of the inputs and merging them. A substantial part of the error in the model predictions is due to errors in the initial condition, and satellites have helped to reduce this error considerably through enhanced spatial and temporal sampling.

Reanalysis data

An issue common to all observations is that complete spatial and temporal coverage is not possible. In situ observations are frequently made at a point and are usually unevenly spaced in, at least, space. Remotely sensed observations tend to be more systematically sampled in space and time, but coverage is frequently not global and the sampling is often insufficient. Furthermore, satellite

OI V2 SST April 2008

Climate Monitoring and Prediction, Figure 3 NOAA OI SST V2 mean sea surface temperature for April 2008, in °C (Reynolds and Smith, 1994).

estimates are nearly always instantaneous whereas our interest for climate is in averages of the data. A polar-orbiting satellite might give a single measurement at a given location once each day, but climate studies require estimates for the whole day. In such cases, a model is often required to obtain estimates which are valid for the whole day.

In the last decade, model reanalysis data has become commonplace in climate science. Such reanalysis techniques are adapted from the data assimilation schemes of operational numerical [weather prediction models](#) and facilitate the combination of multiple observations of multiple parameters and the interpolation of these observations to data-sparse regions in four-dimensional space. Additionally, model forecasts (or nowcasts) can also be made to predict parameters not traditionally measured. Global reanalysis systems therefore provide rich new datasets which can provide data from anywhere in the four-dimensional system (within the model resolution constraints) based on all available in situ and remotely sensed observations. Current reanalysis is still somewhat limited in resolution due to constraints in processing capacity, but are ideal for a range of climate problems.

The first reanalysis to be widely used was the NCAR/NCEP reanalysis (Kalnay et al., 1996) which is still used for a range of purposes and is well suited for many climate monitoring purposes since it is available in near real time. Note that an updated version is now available, the NCEP-DOE AMIP-II Reanalysis (Kanamitsu et al., 2002), which

uses many of the same inputs but corrects a number of issues with the original dataset. The NCAR/NCEP reanalysis directly assimilated radiances from operational TOVS sounders once available (after 1979). Additional remotely sensed datasets were also indirectly used in the analysis as boundary fields. The Reynolds and Smith (1994) SST analysis was used after 1982 when AVHRR data became available and sea ice based on SMMR/SSM/I was used (as well as other non-remote sensing datasets). Another commonly used reanalysis is the European Centre for Medium Range [Weather Forecasting](#) (ECMWF) ERA-40 project which directly assimilated more satellite records than the NCAR/NCEP reanalysis. However, ERA-40 is not available in real time: Analyses from the ECMWF forecast assimilation scheme are available, but the ERA-40 product is not meant for climate monitoring.

The NCAR/NCEP reanalysis starts in 1946, and the ECMWF ERA-40 reanalysis starts in 1958, but much of the satellite data used in both assimilations starts in 1979. This discrepancy has led to discontinuities in the data (Bromwich and Fogt, 2004) which could lead to spurious trend estimates. More recent reanalysis products such as the Japanese JRA-25 (Onogi et al., 2007) and NASA's Modern Era Retrospective Reanalysis (MERRA; <http://gmao.gsfc.nasa.gov/research/merra/>) start in 1979 since remotely sensed observations of the atmosphere make this a far more data-rich period. At present, the ERA-40 reanalysis is not run operationally making it unsuitable for climate monitoring (although the ECMWF

does produce a similar assimilation for their operational model). Additionally, time required for data acquisition and processing make these data unsuitable for some monitoring activities.

Climate prediction

Whether physically or statistically based, predictions of the weather or climate are usually obtained by propagating a set of initial conditions forward to some given time point. In the case of weather forecasting (typically at scales less than 10 days), the focus is on the prediction of the most likely state (e.g., temperature) and individual weather events (e.g., precipitation) (see *Weather Prediction*). In contrast, climate prediction is focused on prediction of the mean state over the next few months, years, or decades. The bulk of all climate models is intended for prediction of climate change effect at the decadal or century scale (Randall et al., 2007). These models are not explored here, and we instead focus on models for seasonal predictions (between 10 days and several months).

Seasonal climate forecasts are made using one of two distinct approaches. The first is to use a dynamical, numerical model such as that used in operational models (see Goddard et al., 2001, for a review). Such models use a physical-based, dynamical representation of the atmosphere similar to those used for numerical weather forecasting. Forecasts are made by using simplified versions of the basic atmospheric and/or oceanic equations to propagate an initial field, usually based on observations. This initial field is largely based on remotely sensed observations, which are assimilated along with other, in situ observations. Seasonal climate predictions made with dynamical models are traditionally deterministic in nature, meaning that a single (hopefully optimal) answer is obtained. However, it is becoming increasingly common for ensemble approaches to be used whereby multiple realizations of the initial conditions are run through the model to assess the effect of measurement error in the initial conditions on the output. This is particularly useful for climate prediction since errors in the initial conditions are relatively small over a short period, but tend to be amplified for longer forecast lead times, an effect that can lead to forecasts being dominated by noise.

Another difference between weather and climate models is the treatment of the ocean and the inclusion of SSTs, which are intimately linked with atmospheric circulation and weather. SSTs change relatively slowly over time, and these changes are often too slow to make a large difference on weather scales. Weather models therefore tend to use only a dynamical atmosphere with prescribed ocean temperatures which are fixed in time. Within a season, changes in SST become important, and so many climate models (seasonal and decadal) use a dynamical ocean. Since the properties of the ocean and the atmosphere are different, it is common to use separate models and *couple* these models so that information passes between the two at set times. For instance, the ocean model

might be run for a day and then the new values used to update SSTs (or other parameters) for the atmospheric model, which in turn might provide wind estimates for the ocean model. Coupled models are an important tool for seasonal climate prediction that have become widely used at a variety of institutions (Stockdale et al., 1998; Graham et al., 2005; Saha et al., 2006; Luo et al., 2008).

The second commonly used approach for seasonal climate prediction is to use a statistical model to make forecasts based on relationships between some observed data and the quantity to be forecast. Statistical models partition the total variance in the data into that which can be explained by the predictor variables and a residual noise component which is modeled by some assumed error distribution. The advantage to this approach is that a full physical understanding of the system being modeled is not required since any unexplained noise is simply modeled in the residual. In practice, statistical prediction models are constructed by using some set of training parameters to develop a model and estimate the parameters of the model. Estimates of the response data are then generated from this model and standard errors (a measure of how incorrect the estimate is) can be generated based on the assumed distribution of the residual noise. Statistical approaches include a wide range of models from linear regression methods to neural networks and canonical correlation analysis. A common requirement of these models is that a lag relationship be known, whereby the predictors contain information about the future state of the response. Among other sources, climate indices such as ENSO and the North Atlantic Oscillation (NAO) have been found to give this lead information, and the ocean is another common input due to its thermal memory. This provides a logical contrast between statistical and dynamical models: Dynamical models rely on direct knowledge of the climate system to infer its future state, whereas statistical models require no knowledge of the system, instead relying on an indirect relationship between two or more variables.

Remotely sensed products play an important role in seasonal predictions as either a direct input to the models (dynamical or statistical) or in a monitoring capacity where they are used to infer the current mean state of the climate and its most likely tendency. Remotely sensed data is also used in a variety of statistical models. Some examples include models to predict rainfall (Nicholas and Battisti, 2008), SSTs (Landman and Mason, 2001), and prevalence of diseases in humans (Linthicum et al., 1999; Thomson et al., 2005) and plants (Boken et al., 2007). Forecasting of ENSO (Mason and Mimmack, 2002; Coelho et al., 2004) is also important since knowledge of its state helps forecasters infer many other weather characteristics and predictions can be used as the base for other forecasts. Additionally, some statistical models use forecast fields from climate models (which assimilate satellite data) to derive estimates (e.g., Hoshen and Morse, 2004; Thomson et al., 2006).

In practice, information from both statistical and dynamical prediction models is used along with the

Climate Monitoring and Prediction, Figure 4 CPC probability of above average, below average, or normal temperature for (a) 8–12 days and (b) 3 months for the United States. Downloaded from the NOAA/NCEP/CPC website: <http://www.cpc.ncep.noaa.gov/on> July 14th 2008.

assessment of the current state of the climate system, and seasonal forecast products are usually composites of multiple forecast and monitoring data. As with weather forecasts, a seasonal forecaster usually compiles the information into a single outlook based on the available products and some knowledge of the relative skill of each data source. This final product takes a variety of different forms, although it is common to have separate forecasts for the near and longer term (approximately 10–20 days and 3–6 months, respectively). Each product usually represents a time-integrated product over the period of interest rather than being an instantaneous value for several months time. One example of such a derived product is the CPC temperature probability product shown in Figure 4. Forecasts are shown for 8–12 days and 3 months as a probability of either above/below average or normal rather than an absolute value. Such metrics are common in seasonal climate prediction where the skill is insufficient to give much more than an indication of the likely state of the climate.

Conclusion

Remote sensing plays a large and varied role in climate monitoring and prediction, providing both the monitoring data and inputs for climate models (statistical or dynamical). At present, our ability to forecast climate is limited by our understanding of the global Earth system and the chaotic nature of the system. While the latter is unlikely to change, it should not be overlooked that current and future research satellite missions have the potential to

improve our understanding and enhance our ability to forecast climate further into the future and with greater accuracy.

Definition

Total weight of cloud water in a vertical column of atmosphere for a unit of area.

Introduction

Clouds play a vital role in modulating climate and the earth's radiation budget. In the atmosphere, the latent heat release or consumption occurs either directly within the clouds or in the precipitation produced from inside the clouds. Clouds strongly affect the radiative fluxes through the atmosphere. Thus, the measurements of hydrometeor variables on clouds in various water phases critically affect the numerical weather prediction (NWP) simulation and climate modeling.

Global measurements of the cloud liquid water path can be determined by satellite-measured microwave brightness temperatures, which quantify the thermal emission of cloud particles. In the early 1970s, the feasibility of the microwave measurement of cloud liquid water was demonstrated by a Nimbus-6 scanning microwave spectrometer. A statistical relationship was first derived between the brightness temperatures at 23 and 31 GHz and cloud liquid water using Nimbus-6 scanning microwave spectrometer data (Grody, 1976). The large-scale distribution of cloud liquid water was obtained over the Pacific Ocean (Grody et al., 1980). This capability was further displayed by Nimbus-7 scanning multichannel microwave radiometer (SMMR) data (Takeda and Liu, 1987). However, more algorithms for cloud liquid water were developed for the Special Sensor Microwave Imager (SSM/I) flown on the defense meteorological

Cloud Liquid Water, Figure 1 Global cloud liquid water retrieved from NOAA-15 Advanced Microwave Sounding Unit (AMSU). Only satellite descending node data are used in this retrieval. Land and sea ice areas are shown as missing because of the incapability of calculating surface emissivity.

satellite program (e.g., Alishouse et al., 1990; Greenwald et al., 1993; Liu and Curry, 1993; Weng and Grody, 1994; Wentz, 1997). The algorithm was further refined for Advanced Microwave Sounding Unit (AMSU) measurements at 23.8, 31.4 GHz (Weng et al., 2003).

Algorithm theoretical database

Cloud liquid water is also referred as the liquid water path. It can be measured from both passive and active remote sensing technology deployed in space and on the ground. From satellites, brightness temperatures at lower microwave frequencies directly respond to the emission signals from clouds and raindrops. Over oceans, the brightness temperatures first increase and then become saturated and decrease as cloud liquid water increases. The nonlinear response is a result of emission and scattering from both small cloud droplets and large raindrops. The saturation point normally varies with frequency and is, for example, 8, 3, and 1 kg/m² (mm) at 10.65, 18.7, and 36.5 GHz, respectively, for a typical warm rain situation. Since the actual liquid water path ranges within several millimeters, it is necessary to use a composite algorithm (Weng and Grody, 1994) to retrieve cloud liquid water to cover the range from non-raining to raining clouds.

In the absence of scattering from precipitation, brightness temperature at a microwave frequency can be derived as the function (Weng et al., 2003):

$$TB = T_s [1 - (1 - \varepsilon)T^2], \quad (1)$$

where ε and T_s are the surface emissivity and surface temperature, respectively, and the atmospheric transmittance is:

$$T = \exp[-(\tau_o + \tau_v + \tau_l)/\mu], \quad (2)$$

where τ_o is the optical thicknesses of oxygen. The optical thicknesses of cloud and water vapor are expressed as $\tau_L = \kappa_L L$ and $\tau_v = \kappa_v V$, respectively, where the liquid water path is $L = \int_0^{\infty} w(z) dz$ and the water vapor path is $V = \int_0^{\infty} \rho_v dz$. The cloud mass absorption

coefficient κ_l is approximated as $\kappa_l = \frac{6\pi}{\lambda \rho_w} \text{Im} \left\{ \frac{m^2 - 1}{m^2 + 2} \right\}$ through Rayleigh's approximation.

Equation 1 provides a fundamental theory for microwave remote sensing of both atmospheric liquid water and water vapor from space over oceanic conditions. In general, at least two frequencies are required, with one being more sensitive to liquid and the other to water vapor. Note that for land conditions

where the emissivity is normally high (typically greater than 0.9), brightness temperature decreases as cloud liquid water increases. The depression from non-raining clouds is also typically very small, less than several degrees Kelvin. Thus, it is difficult to detect the liquid-phase clouds over land where its emissivity is high and variable.

Using two channel measurements at 23.8 and 31.4 GHz from the Advanced Microwave Sounding Unit (AMSU), TB_{23} and TB_{31} , Weng et al. (2003) derived

$$V = a_0 \mu [\ln(T_s - TB_{31}) - a_1 \ln(T_s - TB_{23}) - a_2], \quad (3)$$

and

$$V = b_0 \mu [\ln(T_s - TB_{31}) - b_1 \ln(T_s - TB_{23}) - b_2], \quad (4)$$

respectively, where the coefficients, a_0 and b_0 , are functions of cloud and water vapor mass absorption coefficients, and $a_{1,2}$ and $b_{1,2}$ are functions of surface emissivity and surface temperature, respectively.

The figure below displays a global distribution of cloud liquid water over oceans derived from the use of the AMSU 23.8 and 31.4 GHz measurements. Note that the AMSU measurements during a 24 h period from its descending node do not completely cover the globe because of the presence of orbital gaps. Also, the retrievals are not performed over land, snow, and sea ice conditions due to large emissivity variations. The unit of cloud liquid water is g/m^2 . Note that low clouds over oceans to the west coast of South America are detected very well and their liquid water path is on the order of 100 g/m^2 . The weather systems having relatively high amount of cloud liquid water are associated with those frontal systems and the clouds within the inter-tropical convergence zone (ITCZ) (Fig. 1).

Summary

Satellite passive microwave measurements provide accurate retrievals of cloud liquid water over oceans. It still remains difficult to retrieve cloud liquid water over land from the emission-based algorithms. Further studies will focus on extending the retrievals with more advanced radiative transfer schemes that include scattering from clouds and precipitation. Also, different algorithms should be developed for high and variable emissivity conditions which are typical of land, snow, and sea ice conditions.

CLOUD PROPERTIES

Matthew Lebsock and Steve Cooper
Jet Propulsion Laboratory, California Institute of
Technology, Pasadena, CA, USA

Definitions

Droplet size distribution. The number distribution of water droplets as a function of droplet size.

Cloud optical depth. A unitless measure of the column integrated radiative extinction of a cloud.

Water content. The liquid or ice water content of an atmospheric volume.

Water path. The vertical integral of the cloud water content.

Droplet number concentration. The number of droplets within an atmospheric volume.

Droplet effective radius. A characteristic droplet size defined as the third moment of the droplet size distribution divided by the second moment.

Radar. Radio detection and ranging.

Lidar. Light detection and ranging.

Polarization. A property of electromagnetic radiation that describes the orientation and phase of its oscillations.

Brightness temperature. The blackbody temperature that is inferred from a measured spectral intensity.

Introduction

This entry reviews common remote sensing methods to infer cloud properties. Knowledge of cloud properties is of primary interest because they (1) have a large influence on the reflection and absorption properties of the

Cloud Properties, Figure 1 Relationship between visible $0.66\ \mu\text{m}$ and near-infrared $2.15\ \mu\text{m}$ reflectances for water clouds with optical depths ranging from 0 to 40 and effective radii ranging from 8 to $40\ \mu\text{m}$ for a case with overhead sun and nadir viewing angle.

atmosphere, thus having a profound effect on the Earth's energy balance, and (2) are related to the turbulent and microphysical processes that govern the lifecycle of clouds and the formation of rainfall, thus influencing the cycling of water within the Earth system.

The overarching goal of cloud property remote sensing is to characterize the droplet size distribution of a cloud. The droplet size distribution is highly variable in space and time, and it is therefore common to approximate its character by the integrated water content and the droplet effective radius, which can then be related to analytic functions such as the log-normal distribution or the gamma distribution. The focus here is on satellite remote sensing of cloud microphysical properties; however, it is noted that similar techniques are used to infer cloud properties from ground-based and airborne platforms as well.

Visible and near-infrared techniques

Visible and near-infrared techniques have been developed to simultaneously estimate the cloud optical depth and droplet effective radius from measurements of reflected sunlight in a visible and near-infrared channel (Nakajima and King, 1990). The physical basis for these methods lies in the fact that reflected visible radiation is primarily sensitive to the cloud optical depth, whereas the reflection of near-infrared radiation is largely sensitive to the droplet effective radius. Figure 1 shows an example of these dependencies for liquid clouds. Increasing reflectance in the visible channel corresponds to increasing cloud optical depth, whereas increasing reflectance in the near-infrared channel corresponds to decreasing cloud effective radius. The cloud liquid water path may then be derived from the cloud optical depth and effective radius (Stephens, 1978). Analogous methods are used for the

remote sensing of ice clouds. The visible and near-infrared methods are typified by the MODerate resolution Imaging Spectroradiometer (MODIS) cloud retrievals (Platnick et al., 2003). A notable limitation of visible and near-infrared methods is that they rely on reflected sunlight and therefore may only be performed during sunlit hours.

Microwave techniques

Passive measurements of microwave brightness temperatures have been used to estimate the cloud water path, thus providing a useful integral constraint on the vertical distribution of liquid water content. The physics governing these measurements is that at microwave frequencies, the emission by cloud water may be approximated by the Rayleigh limit (Greenwald, 2009), under which emission is linearly related to cloud water mass. Channels centered near 37 GHz demonstrate the largest signal-to-noise characteristics and dynamic range for the remote sensing of cloud liquid water.

A complication of passive microwave techniques is that the brightness temperatures are also sensitive to the atmospheric temperature and water vapor content as well as the surface temperature and emissivity. Sensitivity to these parameters varies with frequency and measurement polarization. Therefore, passive microwave satellite instruments generally make observations at several frequencies and polarization states, allowing for the simultaneous determination of these properties. The algorithm of Hilburn and Wentz (2008) typifies this approach. A further complication of passive microwave estimates of cloud water path is that they are only possible over oceanic backgrounds where the surface emission is small. The emission from land surfaces is generally large and dominates the much smaller atmospheric emission signal.

Infrared techniques

An infrared method known as the split-window technique exploits differences in radiative properties of cloud particles at two wavelengths in the atmospheric window to estimate ice cloud properties from satellite-observed brightness temperatures. Small particles less than about $30\ \mu\text{m}$, for example, absorb radiation more efficiently at a wavelength of $12\ \mu\text{m}$ than at $11\ \mu\text{m}$. Clouds composed of small particles therefore appear colder at $12\ \mu\text{m}$ than at $11\ \mu\text{m}$ from a satellite perspective. Such radiometric signatures were first exploited by Inoue (1985) to detect thin cirrus. Since the ratio of absorption at the two wavelengths is a function of particle size, the technique can also be used to infer cloud effective radius from the brightness temperature difference (ΔT_b) between the two wavelengths (Prabhakara et al., 1988). Infrared radiative transfer (see entry *Radiative Transfer, Theory*) calculations for a set of cloud properties resemble an “arch,” as seen in Figure 2. The right foot of the arch corresponds to the clear-sky emitting temperature of the atmosphere, while the left foot represents an optically thick cloud where observed brightness temperatures approach the

Cloud Properties, Figure 2 Relationship between TB (11 μm) and BTD (11–12 μm) for cirrus clouds with optical depths ranging from 0 to 10 and effective radii ranging from 8 to 32 μm . The clouds are composed of randomly oriented randomized hexagonal ice aggregates (Baran et al., 2003) and have a temperature of 217 K.

Cloud Properties, Figure 3 Theoretical relationship between liquid water content and reflectivity for three different values of number concentration (N) using the equations of Matrosov et al. (2004).

cloud thermodynamic temperature. Intermediate values provide information on cloud properties. Cloud optical depth is found from T_{b11} along the x-axis and cloud effective radius from ΔT_b along the y-axis. Since the technique has sensitivities limited to thin clouds and small particles, it has been applied infrequently at the operational scale. Heidinger and Pavolonis (2009), however, produced a global, multi-decadal set of cloud properties from the split-window technique based upon the AVHRR Pathfinder Atmospheres Extended dataset.

Visible polarization techniques

The polarization state of reflected visible radiation can be used to determine the effective radius of liquid clouds (Bréon and Goloub, 1998). The physical basis for this technique lies in the observation that at scattering angles between 150° and 170° liquid clouds produce cloud-bow features in the polarized reflection. The angular and spectral characteristics of these cloud-bows may be used to determine the liquid cloud effective radius quite accurately. Use of this technique is limited to sunlit hours over large homogenous cloud layers and is therefore not globally applicable. Despite its limited applicability, it has been used to identify high biases of approximately 2μ in effective radius estimates from the less accurate visible and near-infrared techniques (Bréon and Doutriaux-Boucher, 2005).

Active techniques

The successful flight of the CloudSat cloud profiling radar and the CALIOP lidar has permitted active techniques for the remote sensing of cloud properties from space. These instruments transmit discrete pulses of radiation and then

measure the backscattered signal as a function of time from transmission resulting in a vertical profile of backscattered reflectivity. A major advantage of active methods over passive methods is that they provide precise cloud boundaries and observed vertical profiles of the cloud microphysical quantities.

Radar profiling of cloud water content relies on either physical or empirical relationships between the cloud water content or cloud effective radius and the backscattered reflectivity that take the form of a power law (Matrosov et al., 2004). Figure 3 shows some relationships between reflectivity and cloud water content. Note the wide distribution of relationships between the cloud water content and the reflectivity, which results in a large uncertainty in the cloud property retrievals without the addition of an integral constraint. Integral constraints that have been proposed include the cloud optical depth (Austin and Stephens, 2001) or an ancillary passive microwave observation (Dong and Mace, 2003).

Detection of clouds with cloud radar is limited by the radar minimum detectable signal. Clouds that are too thin or composed of small droplets can create reflectivities that lie below the minimum detectable signal. However, the strong lidar backscattering signal permits detection of these clouds. This situation is particularly common with thin cirrus and stratus clouds. Methods analogous to those using radar have been developed to estimate ice cloud microphysical properties from the lidar backscatter when the radar signal falls below the minimum detectable signal (Delanoe and Hogan, 2008). These lidar methods are not feasible for water clouds because of the strong attenuation of the lidar beam by liquid water.

Summary

This entry reviews the primary methods by which cloud microphysical properties have been estimated from satellite remote sensing. The common methods covered include visible and near-infrared, passive microwave, infrared, visible polarization, and active techniques. Each of these techniques has their own strengths and weaknesses and offers a unique piece of information regarding cloud properties. A topic of current research in cloud remote sensing is understanding the synergies between these various methods and determining how they might best be combined to more accurately estimate cloud properties.

Acknowledgments

This research was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the NASA.

COASTAL ECOSYSTEMS

Xiaojun Yang
 Department of Geography, Florida State University,
 Tallahassee, FL, USA

Coastal zone; Littoral ecosystems

Definition

Coastal ecosystems are typically found at a physical region extending from the edge of the continental shelf to the intertidal and nearshore terrestrial area. They include saline, brackish, and freshwaters, as well as coastlines and the adjacent lands that can extend to the entire coastal watershed. Globally, coastal ecosystems comprise a wide array of nearshore terrestrial, intertidal, benthic, and pelagic marine ecosystems.

Introduction

Coastal ecosystems, by virtue of their position at the interface between truly terrestrial and oceanic ecosystems, belong to the most dynamic and productive ecosystems on Earth. They are among the most important ecosystems, providing numerous ecological, economic, cultural, and aesthetic benefits and services. Although they comprise only 20 % of all land area, coastal areas are now the home of nearly half of the global population (Burke et al., 2001). Increased coastal population and intense development threaten and degrade global coastal ecosystems, placing an elevated burden on organizations responsible for the planning and management of these sensitive areas (Hinrichsen, 1998; Hobbie, 2000; National Research Council, 2000; Selman et al., 2008).

Coastal ecosystem management involves the procedure of monitoring which is based on a reliable information base. Conventional field-based mapping methods are still vital but often logistically constrained. Because of cost-effectiveness and technological soundness, remote sensing has increasingly been used to develop useful sources of information supporting decision making for various coastal applications (e.g., Yang et al., 1999; Yang, 2005a, b, 2008, 2009a, b). But coastal environments challenge the applicability and robustness of remote sensing because they exhibit extreme variations in spatial complexity and temporal variability (Klemaš, 2009). Encouragingly, recent innovations in data, technologies, and theories in the wider arena of remote sensing have provided scientists with invaluable opportunities to advance the studies on coastal environments.

Given the above context, this entry will review several major types of coastal ecosystems, followed by a discussion on how remote sensing can be used to characterize coastal waters, submerged aquatic vegetation, benthic habitats, coastal wetlands, and watersheds. It will finally highlight several areas that need further research and development.

Major coastal ecosystems

Comprehensive reviews on various coastal ecosystem types are given elsewhere (e.g., Mann, 2000; Beatley et al., 2002). Our current discussion targets several types of coastal ecosystems including estuaries, benthic systems, sea grass systems, coastal marshes, and mangroves, because they have been extensively studied by remote sensing. Note that these ecosystems are largely recognized according to the main primary producer with the exception of estuaries. As a rather large ecosystem, estuaries can include the other four as subsystems, but the latter may also occur outside an estuary.

Estuaries are partially enclosed bodies of coastal waters typically found where freshwater from rivers meet with saltwater from the ocean. They are often known as bays, lagoons, harbors, inlets, sounds, or fjords. Estuaries are important ecosystems, providing goods and services that are ecologically, economically, and culturally indispensable. Ecologically, estuaries are not only the “nurseries of the sea,” providing habitats for many marine organisms, but also serve as a natural buffer that filters out much of the sediments and pollutants carried in by terrestrial runoff, creating cleaner water that eventually benefits both human and marine life. Economically, estuaries support significant fisheries, tourism, and other commercial activities and the development of important public infrastructure, such as harbors and ports. Culturally, estuaries are often the focal points for recreation, commerce, scientific research and education, and aesthetic enjoyment.

The benthic system is the community of organisms living on the bottom of oceans in areas not colonized by macrophytes (Mann, 2000). Benthic habitats are virtually bottom environments with distinct physical, chemical, and

biological characteristics. They vary widely depending upon their location, depth, salinity, and sediment. Benthic habitats in areas with depth greater than 200 m have been much less commonly observed and mapped. Estuarine and nearshore benthic habitats can be highly diverse, including submerged mudflats, rippled sand flats, rocky hard-bottom habitats, shellfish beds, and coral reefs. Note that sea grass beds can be described as a benthic system, but they are treated separately (see above). In terms of ecological functioning, the benthic system serves as the site of nutrient regeneration and the site of considerable secondary production that is utilized by important predators, such as bottom-feeding fish and crustaceans (Mann, 2000).

Sea grass are aquatic flowering plants that live fully submerged in the saline coastal environment and are also called “submerged aquatic vegetation.” Sea grass can form extensive beds or meadows, dominated by one or more species. They are distributed worldwide in soft sediments from mean low tide level to the depth limit determined by the penetration of light that permits sea grass plants to photosynthesize. Sea grass beds are a highly diverse and productive ecosystem, and they almost always support more invertebrates and fish than the adjacent areas lacking sea grass (Mann, 2000). Sea grass beds provide coastal zones with a number of ecosystem goods and services, such as fishing grounds, wave protection, oxygen production, and protection against coastal erosion.

Coastal marshes are predominately grasslands that are periodically flooded by tides in the intertidal regions. The salinity from salt or brackish tidal waters creates a salt-stressed aquatic environment where halophytic plants thrive. Coastal marshes may be classified as salt marshes, brackish marshes, and freshwater tidal marshes. They may be associated with estuaries and are also along waterways between coastal barrier islands and the inner coast. Coastal marshes are of great ecological values because they serve as the nursery grounds for fish, habitats for a wide variety of wildlife, and the buffer zones to protect water quality.

The mangrove ecosystem is commonly found in tropical and subtropical tidelands throughout the world. The mangrove family of plants dominates this coastal wetland ecosystem due to their ability to thrive in the saline coastal environment. The three mangrove species commonly grown in the USA are red, black, and white mangroves. The term “mangroves” can narrowly refer to these species but most commonly refers to the habitat and entire plant assemblages. Because mangroves are constantly replenished with nutrients, they sustain a huge population of organisms that in turn feed fish and shrimp, which further support a variety of wildlife; their physical stability helps prevent shoreline erosion, shielding inland areas from damage during severe storms and waves.

Remote sensing of coastal ecosystems

Modern remote sensing technology began with the invention of the camera more than one century ago, and by now, a large number of remote sensing systems have

Coastal Ecosystems, Table 1 Characteristics of selected current and future satellite remote sensing systems relevant to coastal environments

Satellite/sensor	Date launched or planned	Spectral range and bands	Spatial resolution	Radiometric resolution (bit)	Revisit (day)	Swath width (km)	Specific coastal applications
OrbView-2/SeaWiFS	1 August 1997	0.402–0.885 μm 8 bands	1.1 km	10	1	2,800	Ocean color, phytoplankton, ocean carbon cycle

been developed to measure energy patterns from different portions of the electromagnetic spectrum (see Jensen, 2007). Many such systems have been originally designed for terrestrial or open-ocean applications, among which some are relevant to coastal environments (Table 1). The following sections will provide an overview on remote sensing of coastal waters, submerged aquatic vegetation, benthic habitats, coastal wetlands, and watersheds. Note that for each application, acquiring accurate and consistent in situ data using ships, buoys, and field instruments is needed in the calibration and validation of remote signals and in algorithm development.

Remote sensing of coastal water quality indicators, such as chlorophyll-*a*, turbidity, dissolved organic matter (DOM), total nitrogen, temperature, and salinity, relies on the use of either a radiative transfer (see entry *Radiative Transfer, Theory*) algorithm or a statistical regression model. Airborne remote sensing systems are most useful for small, shallow, or optically complex coastal waters. Several existing spaceborne color scanners primarily designed for open oceans are of limited usefulness for nearshore coastal waters due to their relatively coarse spatial resolutions. Some researchers have been successful in remote sensing of nearshore coastal and estuarine waters by using satellite data from terrestrial sensors, such as Multispectral Scanner (MSS), Thematic Mapper (TM), Thematic Mapper Plus (ETM+), SPOT HRV, IKONOS, and QuickBird (see Yang, 2005b, 2008, 2009a, b). Compared to multispectral radiometers, hyperspectral sensors offer extremely high spectral resolution that can help discriminate complex bio-optical properties of coastal waters.

Mapping benthic habitats and submerged aquatic vegetation (SAV) can be accomplished through image interpretation or automated classification. The image interpretation approach is particularly suitable for aerial photography or high-resolution satellite imagery. It is based on the synthetic use of various image elements such as tone, pattern, texture, shape, size, and association in the identification and delineation. Individual benthic habitats or SAV polygons can be delineated manually or through an on-screen digitizer. Some field samples obtained through various instruments such as underwater video and still photography are needed to help develop image interpretation keys and verify the mapping accuracy. This image interpretation method can produce accurate results although it is quite labor intensive and highly dependent upon the skills and experience of an interpreter. On the other hand, there are various image classification methods, either supervised or unsupervised, which can be used for benthic habitat or SAV mapping. Image fusion from high-spectral- and high-spatial-resolution sensors can help improve the accuracy of benthic habitat or SAV mapping (Mishra, 2009). Change-detection analysis of benthic habitat or SAV can be made by using change vector analysis, principal component analysis, or map-to-map comparison.

Remote sensing has been used in wetland (including mangroves) mapping for several decades. Early inventories were largely based on the interpretation of aerial

photographs. Automated classification of satellite imagery facilitates the mapping of the spatial distribution of wetlands and the estimation of biomass or net productivity over a large area. Under unfavorable weather conditions, microwave or radar products can be used to help identify broad wetland classes. For species differentiation of wetland plants, broadband remote sensors may be problematic due to their inability to provide sufficient spectral details. Hyperspectral remote sensing allows the detection of subtle differences in canopy density, leaf and canopy structure, and biochemical properties, which can be further used to distinguish coastal wetland plant species. Additionally, LIDAR remote sensing can help estimate canopy structure of shrubs, marsh, grass, and other vegetation found in the littoral zone. The integration of spectral imagery and LIDAR data offer the potential to significantly improve the species classification and structural mapping of coastal plant communities (Nayegandhi and Brock, 2009).

Watershed landscape characterization affects coastal water quality by altering sediment, chemical loads, and hydrology, and therefore information on upstream landscape structure and patterns is indispensable for coastal ecosystem assessment. Remote sensing of coastal watershed landscape structure and patterns generally involves procedures of land cover map production and landscape metrics computation. Aerospace imagery from various terrestrial sensors, especially those equipped with a blue band, can be used to map land cover types in coastal watersheds. The production of an accurate land cover map for a coastal area is not a trivial task, mainly due to the presence of a variety of wetlands and vegetation covers, along with complex urban impervious materials and agricultural lands. Several strategies have been developed to improve automated land cover classification, which include GIS-based hierarchical classification and spatial reclassification, knowledge-based expert systems, artificial neural networks, fuzzy logic, and genetic algorithms. Landscape metrics can be derived from a land cover map, by which the landscape structure and pattern of a coastal watershed can be further assessed (Yang, 2009a).

Further research

This entry reviews several major coastal ecosystems and discusses how remote sensing can be used to characterize coastal waters, benthic habitats and submerged aquatic vegetation, coastal wetlands (including mangroves), and coastal watershed landscape characteristics.

While some significant progress has been made in remote sensing of coastal ecosystems, there are several major areas that deserve further research. Firstly, the current ocean color scanners are basically designed for offshore waters and are of limited usefulness for optically complex nearshore waters. Further research is needed to help design future ocean color radiometers appropriate for shallow coastal waters. Secondly, most of the algorithms for retrieving water quality measures were originally designed for open-ocean waters, and a significant

area for continuing research is the fundamental understanding of the functional linkage between water constituents and remote reflectance for coastal waters. Thirdly, more research is needed to advance the fundamental understanding of the relationship between the volumetric reflectance, the canopy density of SAV populations, water depth, and bottom reflectance parameters. This will help develop more realistic volumetric reflectance models, thus increasing the likelihood of accurate SAV mapping. Fourthly, there is an increased research demand to develop improved methods and technologies for resolving the spectral confusion between different land cover classes from medium-resolution imagery and for incorporating image spatial characteristics and ancillary data to improve land cover classification from high-resolution imagery. Fifthly, more research is needed to advance the fundamental understanding of the relationship between landscape patterns and ecological processes. Lastly, continuing research efforts are needed to help acquire good and sufficient in situ data for building comprehensive spectral libraries of different coastal plant species and for calibrating remote signals and verifying information extraction algorithms for coastal environments.

COMMERCIAL REMOTE SENSING

William Gail
 Global Weather Corporation, Boulder, CO, USA

Definition

Commercial. Pertaining to organizations or activities associated with buying and selling products and services.

Introduction

Commercial remote sensing is remote sensing that produces information intended for sale on open commercial markets. It is generally performed by companies or through public-private partnerships rather than by governments. The commercial market includes remote sensing performed primarily from aerial and spaceborne

platforms. Due to the strategic nature of remote sensing, commercial interests are nearly always intertwined with national interests, at least for spaceborne systems. Governmental policies authorizing and regulating commercial remote sensing generally reflect objectives for national security, technology development, international relations, and economic positioning. The history of the industry, and its current configuration, reflect this tension between economic and national interests. Demand for commercial remotely sensed data has increased in recent years, in part due to the widespread availability of geographic information systems (GIS) that can display and analyze the imagery and online means for distributing the results.

History

Aerial commercial remote sensing has been in existence for nearly a century. A significant focus of the industry is photogrammetry, the making of geometrically accurate high-resolution image mosaics covering large areas such as cities and states. Today, such mosaics are routinely produced with image resolutions as good as 15 cm and sometimes better. Until recently, the mosaics were generally panchromatic, but color imagery has become common with the introduction of digital sensors during the 2000s. In addition to optical photogrammetry, commercial remote sensing includes work with synthetic aperture radar (SAR), hyperspectral imagers, and LIDAR sensors. Both SAR and LIDAR are commonly used for measuring topography and related three-dimensional imaging. The aerial remote sensing industry consists of both commercial and government-owned entities, often in competition.

The roots of spaceborne commercial remote sensing extend back to the early 1970s with efforts by the USA, France, and India to provide commercial adjuncts to their national Earth monitoring systems. These early efforts laid the groundwork for today's industry with several dozen commercial systems in operation and a global market that is multibillion dollars (Modello et al, 2004).

In 1972, the USA launched the Earth Resources Satellite 1, which was subsequently renamed Landsat. In part a Cold War effort to demonstrate US leadership in Earth resources monitoring, its commercial value became recognized soon after launch. By the early 1980s, with the various interested parties all seeking a better way to access Landsat's imagery (National Research Council, 1985), a strong effort was made to change the regulatory environment governing Landsat. The result was the Land Remote Sensing Commercialization Act of 1984, which for the first time established the basis for commercial remote sensing operations authorized by the USA. As a result, in 1985 Landsat was partially privatized through a partnership with Earth Observation Satellite Corporation (EOSAT), itself a partnership of Hughes Aircraft and RCA. EOSAT was given a contract to operate the system for 10 years and build follow-on satellites, obtaining rights for commercial sale of the data.

Around the same time, the French *Système pour l'Observation de la Terre* (SPOT) satellite series was being developed. To encourage commercialization, a public-private partnership called Spot Image was created by the French government in 1986. They have since launched a series of increasingly capable satellites, starting with the 10 m resolution SPOT-1 in 1986. In India, the Indian Space Research Organization (ISRO) initiated a commercially oriented Earth-observing program following the success of their early demonstration satellites Bhaskara-1/2 launched in 1979 and 1981. The Indian Remote Sensing (IRS) series of satellites was initiated with the IRS-1 launch in 1988 and continues as a robust program today.

As demand grew and technology improved, these early efforts spurred further commercial interest beginning in the 1990s. The first truly commercial (not public-private partnerships) remote sensing satellite operations were plagued by early failures. EarlyBird was launched by EarthWatch (originally called Worldview and changed in 2001 to DigitalGlobe) in 1997 but functioned for only 3 days. Space Imaging launched their first satellite Ikonos in 1999 but it failed to reach orbit. Space Imaging succeeded with their second Ikonos satellite later in 1999. EarthWatch's second satellite, QuickBird, also suffered a launch failure in 2000, but the third satellite Quickbird-2 succeeded in 2001. ORBIMAGE joined the group in 2003 with the launch of Orbview-3, but only after Orbview-4 was lost on launch. By the early 2000s, these firms had become increasingly dependent on contracts from the US National Geospatial-Intelligence Agency (NGA) for revenue. In 2005, ORBIMAGE acquired Space Imaging for \$58 million after it failed to win the latest rounds of NGA contracts. ORBIMAGE subsequently renamed itself GeoEye.

More recently, the intelligence community has been a significant partner in the development of commercial remote sensing capability. In the USA, large data purchase contracts such as NextView, ClearView, and EnhancedView by NGA have provided anchor funding for commercial remote sensing companies. NextView contracts, for example, are service-level agreements that specify requirements for imagery purchases from satellites still to be developed. They are designed to provide a long-term government partnership commitment that enables the private sector partner to finance and develop new satellites that meet the requirements. To motivate a commercial market, the agreements are nonexclusive, meaning that the companies can sell the same imagery to other customers. A 2007 independent report chartered by the US National Reconnaissance Office (Marino, 2007) defined various approaches for intelligence community use of commercial remote sensing along with the benefits and risks of those approaches.

The Landsat Data Continuity Mission, initiated in the early 2000s as the follow-on to Landsat-7, was originally envisioned as a strong public-private partnership but has since evolved into a more traditional system acquisition with the government retaining responsibility for data

processing and distribution. NASA also used the Sea-viewing Wide Field-of-view Sensor (SeaWiFS) mission to promote commercialization. SeaWiFS was built for NASA under partnership with Orbital Sciences Corporation and launched in 1997. ORBIMAGE (renamed GeoEye), a spin-off from Orbital Sciences, was given the responsibility for operating the satellite (renamed Orbview-2 for commercial purposes) and for selling the data, with NASA itself purchasing data.

The mid-2000s saw the entrance of many new commercial players with innovative approaches to the market. RapidEye, a public-private partnership, developed and launched a series of five satellites designed to provide rapid-refresh multispectral optical imagery. The TerraSAR satellite system owned and operated by InfoTerra, another public-private partnership, focused on SAR imagery. Surrey Satellite Technology Ltd. (SSTL) developed a multi-government collaboration that built and launched a series of small satellites called the Disaster Monitoring Constellation (DMC), each owned and controlled by a different government (Algeria, Nigeria, Turkey, Britain, China, Spain) but operated jointly through a wholly owned subsidiary of SSTL called DMC International Imaging.

Despite today's successes, a number of companies with ambitious commercial business plans have attempted to enter the market and failed. Resource21 was focused on providing short-revisit multispectral imagery for use in agriculture starting in the 1990s. Their plans for a satellite system focused on this market did not proceed. Around the same time, AstroVision began pursuing a new market for imagery taken from geostationary orbit but had not been able to develop the system after more than a decade. In 2011, RapidEye filed for the German equivalent of bankruptcy protection. Even after several decades of market development, spaceborne commercial remote sensing remains a risky business with considerable investment and high likelihood of failure (National Research Council, 2002; Group on Earth Observations, 2005).

Technology

Of the many spaceborne remote sensing technologies developed over the years for scientific and defense purposes, those that have been commercialized are largely constrained to high-resolution imagery. Initially, this meant panchromatic optical imagers, although inclusion of color bands quickly became routine. One current trend is an increase in the number of color bands and the extension of these bands to infrared wavelengths. Hyperspectral imagers represent the next logical step in this progression, although no company has yet announced plans for doing so. Canada pioneered use of synthetic aperture radar in the commercial realm, with the 1995 launch of Radarsat, and a number of commercial radars are operating now. A significant technology advance occurred with the reduction in size and weight of spacecraft platforms, allowing the introduction of low-cost multi-satellite

constellations such as DMC and RapidEye. A number of companies have built businesses around the sale of satellite systems and technology to nations that do not have the capability to build their own.

Aerial remote sensing technologies have followed a somewhat different path. Because aerial systems allow access to the sensor itself, film remained a viable sensing medium far longer than with spaceborne systems. In the early 2000s, highly capable digital aerial cameras were introduced, and by 2010 most of the industry had transitioned to digital imagery. Related technologies, such as widespread availability of GPS positioning and accurate inertial sensors, made digital sensors even more effective.

Regulation

Commercial remote sensing is regulated on a nation-by-nation basis, involving both policy and law. In general, the purpose of such regulation is to make data available for legitimate scientific and commercial uses while at the same time protecting national security interests (Gabrynowicz, 2007). A critical aspect of such regulation is the use of licensing that authorizes companies to operate commercial remote sensing systems and defines the constraints on that operation. Central to this are rules for ownership, dissemination, and use of data, particularly with regard to resolution and timeliness of distribution.

The most developed regulatory framework is that of the USA. The earliest formal legislation was the *Land Remote Sensing Commercialization Act of 1984*, a by-product of the Reagan-era policies to promote privatization of government assets. The Act was driven by the specific need to create better access to Landsat imagery, but it also introduced a more general framework for licensing and regulation of commercial remote sensing systems. This was updated through the *Land Remote Sensing Policy Act of 1992*, which reversed the commercialization of Landsat contained in the 1984 Act, but provided further legislation promoting private sector remote sensing.

Despite these legislative acts, uncertainty remained regarding how licensing of commercial remote sensing systems would actually occur. This uncertainty was initially resolved in 1994 through a presidential policy statement known as the *US Policy on Foreign Access to Remote Sensing Space Capabilities* (PDD-23). It stated clearly the dual-purpose policy goal: "the fundamental goal of our policy is to support and to enhance US industrial competitiveness in the field of remote sensing space capabilities while at the same time protecting US national security and foreign policy interests." PDD-23 provided the administrative mechanisms needed to make the 1992 legislative act effective, including four fundamental principles: (a) the presumption that US licenses would only be issued for systems with capability no better than what is commercially available from other suppliers in the world marketplace, (b) tight control of technology exports in the form of satellite systems and components,

(c) management of system capabilities (rather than data distribution) as a means for constraining imagery access by undesirable parties, and (d) “shutter control” that allows the government to stop all commercial remote sensing when appropriate national interests are identified.

Licenses are further constrained by an amendment to the 1997 Defense Authorization Act (known as the Kyl-Bingaman amendment) that specifically limits imagery taken over Israel to no better than that “available from commercial sources.” Throughout much of the 1990s, for example, this limit was set to 2 m. The *Commercial Remote Sensing Policy of 2003* (NSPD-27), which superseded PDD-23, did not change these licensing provisions but strengthened the commercial sector by encouraging drawing on commercial capabilities to the “maximum practical extent” when serving government needs.

Under this framework, authority for licensing commercial remote sensing is allocated to the Department of Commerce. Within the Department of Commerce, the NOAA Office of Space Commercialization provides policy guidance while licenses themselves are issued by the NOAA Commercial Remote Sensing Regulatory Affairs Office. Between 1993 and 2000, 17 licenses were issued. In 2008, a total of 19 licenses were active covering 45 satellites with 10 launched. This office is advised in the effort by an independent board called the Advisory Committee on Commercial Remote Sensing (ACCRES). NOAA is responsible for assessing the state of the industry and determining, for example, the resolution of systems that can be licensed. Among the provisions included originally in licenses is that no imagery can be distributed for at least 24 h after it is collected, a constraint designed to minimize use of US-collected imagery by enemies for targeting US military positions. After lengthy interagency governmental deliberation, this provision was dropped in 2007.

Canada also has a relatively mature and transparent regulatory framework built around the *Canadian Space Agency Act of 1990* and the *Remote Sensing Space Systems Act of 2005*. The USA and Canada have a formal agreement concerning operation of commercial remote sensing systems. India, on the other hand, has no relevant law but rather a comprehensive set of policies (Rao et al., 2002; Gabrynowicz, 2007). In Germany, regulation is provided through the *2008 Satellite Data Security Law*, which specifies that approval for commercial remote sensing activities is applied not to each satellite development but rather to each data request on a case-by-case basis. Japan established a *Basic Space Law* in 2008 and released a *Basic Plan for Space Policy* based on that law in 2009. Other nations tend to have less open or less specific regulatory guidelines or to regulate on a satellite-by-satellite basis (Gabrynowicz, 2007). Some govern commercial remote sensing through general space policies, while others have only informal policies. Only a limited amount of international agreement is available to guide commercial remote sensing. In 1986, the United Nations released

a set of principles concerning remote sensing from space (United Nations, 1986), reflecting the desire for remote sensing activities to be used for the benefit of all nations.

Current examples

Three recent trends have had enormous impacts on aerial remote sensing. The first is the transition from analog to digital technologies within optical imagers, as discussed previously. Alternate sensing technologies, including radar and LIDAR, are still establishing their niches within overall commercial offerings. The second is advances in computers and software, making it feasible to work with large imagery volumes in professional domains such as GIS and photogrammetry. The third is end-user applications, such as online mapping, that make such imagery and related value-added products accessible to consumers. Today, there is a robust commercial industry dedicated to the collection of aerial remote sensing and related industries for value-added products, software, and instrument development. Despite these technology changes, the industry business models have evolved more slowly and remain characterized by smaller companies. The nature of the industry varies widely by country, with some less robust due to strong competing government capabilities.

For the foreseeable future, high-resolution electro-optical imagery will remain the central focus of spaceborne commercial remote sensing. At the present time, the USA retains leadership in the area of commercial electro-optical imagery, but other nations lead in the area of radar imagery. Considerable innovation is being applied to introduce capabilities such as rapid revisit and advanced multispectral imagery that serve customers beyond those needing the highest resolution.

GeoEye’s latest satellite GeoEye-1 was launched in 2008 and was developed with funding raised in part through an NGA NextView contract. GeoEye-1 provides panchromatic imaging with 0.41 m resolution (although the operating license requires this to be resampled to no better than 0.5 m before distribution) and multispectral imagery with resolution 1.7 m. A second GeoEye satellite is expected sometime by 2013. DigitalGlobe’s Worldview-1 (launched 2007), also funded in part through an NGA contract, produces 0.5 m panchromatic imagery. Worldview-2 (launched 2009) provides 0.46 m panchromatic imagery and 8-band color with 1.8 m resolution. DigitalGlobe also operates the older QuickBird satellite.

Spot Image operates several SPOT satellites and began launching the more advanced Pleiades series beginning in 2011. The Pleiades satellites provide panchromatic imagery at 0.7 m resolution and 4-band color at 2 m resolution. Spot Image also has distribution rights to other national systems, including Korea’s KOMPSAT and Republic of China’s FORMOSAT. Russia launched the Resurs-DK1 satellite, with 0.9 m resolution, in 2006 and markets data through SOVZOND JSC. Russia has also leveraged imagery from older surveillance satellites, digitizing that

imagery and selling it through commercial channels. The Israeli EROS-A/B imagery satellites, launched between 2000 and 2006 with resolution as good as 0.7 m, are owned and operated by an Israeli-founded international company ImageSat International.

The Indian Remote Sensing (IRS) series of satellites is the largest single commercially oriented remote sensing system in the world. It now includes three satellite classes focused on land resources, ocean resources, and cartography. ResourceSat-1/2 satellites, launched in 2003 and 2009, have 6 m pan resolution and 3-band color at the same resolution. OceanSat-2 was launched in 2009 and focused on ocean color imaging, carrying an 8-band multispectral imaging and Ku-band scatterometer. The Cartosat series has had four launches starting in 2005, with pan resolution better than 1 m. Commercial image distribution is the responsibility of ISRO's commercial entity Antrix.

Within eastern Asia, neither China nor Japan has commercial remote sensing capability, though each has a robust remote sensing program. The Korean KOMPSAT-1/2 satellites, launched in 1999 and 2006 by the Korean Aerospace Research Institute (KARI), have resolution of 4-band color with 4 m resolution. The Republic of China FORMOSAT-1/2 series, launched in 1999 and 2004, have a resolution of as good as 1 m and 4-band color with 8 m resolution. The imagery from both KOMPSAT and FORMOSAT is currently marketed by Spot Image.

Several companies have pursued somewhat different approaches to the commercial market, focusing on improved repeat cycles rather than highest resolution. Surrey Satellite Technology Ltd. (SSTL) developed a multi-government collaboration that built and launched a series of small satellites called the Disaster Monitoring Constellation (DMC), each owned and controlled by a different government (Algeria, Nigeria, Turkey, Britain, China, Spain) and operated jointly through a wholly owned subsidiary of SSTL called DMC International Imaging. The German RapidEye satellite constellation, a five-satellite system designed for rapid-refresh multispectral imagery, was developed as a public-private partnership with a diverse set of public and private investors largely from Germany and Canada. The satellites were launched on a single launch vehicle in 2008.

Radar imagery has proven to be of strong commercial interest. Radarsat International was formed in 1989 by a consortium of Canadian companies with the purpose of processing and distributing the data from Radarsat-1, launched in 1995. One of the shareholders, Macdonald Dettwiler and Associates, bought out the others in 1999 and formed a deeper partnership with the Canadian government to build and operate Radarsat-2, launched in 2007. The Radarsat-2 resolution of 3 m substantially improved on the 8 m resolution of Radarsat-1. TerraSAR-X, launched in 2007, is a public-private partnership between EADS (through their InfoTerra company) and the German Aerospace Center (DLR). It produces radar imagery with resolution up to 1 m including a variety of multipolarization and interferometric data

products. A companion satellite, TanDEM-X, was launched in 2010, allowing the system to operate in interferometric mode so as to perform high-resolution topographic mapping. COSMO-SkyMed is a dual-use system of four satellites with 1 m resolution and polarimetric/interferometric capability funded by the Italian Space Agency, the Italian Ministry of Defense, and the commercial company Telespazio. The first launch was in 2007 and the last in 2010.

Summary

The commercial market today is served by both aerial and spaceborne sectors, with some overlap. Over the last decade, the relative roles of each sector have become more clearly defined within the market. The aerial sector continues to be dominated by smaller companies and governmental entities, with significant national and even regional variability. The spaceborne sector is moving rapidly from an early exploratory phase, in which new technologies, business models, and regulatory environments were being assessed, to a mature phase with well-established success paths. The entire space industry is becoming more commercialized, from launch vehicles to spaceports, establishing a positive context within which remote sensing's own commercialization takes place. The remote sensing industry as a whole is moving from a platform-centric view to a services-centric view in which the features of the data are more important than the features of the sensors. Governments are becoming more focused on remote sensing as an important element of their space programs. They are migrating to smaller but more capable satellites, and they view commercialization or dual use as an important element of their efforts. Capabilities of commercial systems are increasingly diverse, from the growing use of radar to the selection of optical bands to the availability of short-revisit imagery. All trends suggest that the importance of commercial remote sensing will continue to grow in the coming years.

COSMIC-RAY HYDROMETEOROLOGY

Darin Desilets¹ and Marek Zreda²

¹Hydroinnova LLC, Albuquerque, NM, USA

²Department of Hydrology and Water Resources,
University of Arizona, Tucson, AZ, USA

Definitions

Cosmic-ray hydrometeorology. The science of measuring hydrologic variables through their effects on secondary cosmic-ray intensity.

Primary cosmic ray. A charged particle, usually a proton, traveling toward Earth at relativistic speed.

Secondary cosmic ray. An energetic proton, neutron, or other subatomic particle generated as a consequence of primary cosmic rays colliding with the Earth.

Introduction

Cosmic rays continually bombard Earth, giving rise to a small but measureable flux of background neutrons at the land surface. These ambient neutrons respond strongly to the presence of land surface water in the form of soil moisture and snow or more specifically to the hydrogen which that water contains. The unique ability of hydrogen to influence neutron intensity has been known since the discovery of the neutron itself in the 1930s, when the mysterious nonionizing radiation was first identified through its ability to scatter hydrogen nuclei from paraffin (Chadwick, 1932), losing substantial fraction of its energy in the process. By the late 1950s, soil scientists began applying neutron scattering principles to the field determination of soil water content by lowering radioisotopic neutron sources and colocated neutron detectors down bore holes and measuring the intensity of backscattered neutrons (Gardner and Kirkham, 1952). It was later demonstrated that water content in the shallow subsurface and snow water equivalent depth could be obtained passively by measuring background cosmic-ray neutrons with detectors buried in the top meter of soil (Kodama et al., 1985), although the method was never widely adopted. More recently, Zreda et al. (2008) showed the feasibility of noninvasively measuring soil water content through

aboveground measurements of cosmic-ray neutron intensity. This technique operates at a scale of tens of hectares, which fills an important gap between the scales of invasive point measurements and satellite remote sensing footprint.

Neutron interactions in soil

The transmission of fast neutrons through bulk matter is profoundly influenced by the presence of hydrogen, which at the land surface is present mainly in the form of liquid and solid water and plant carbohydrates. Hydrogen is uniquely effective in moderating (slowing) neutrons by virtue of its low mass and relatively large elastic scattering cross section, which is a measure of the probability of interacting elastically with a neutron. As with any two particles having the same mass, a fast neutron can theoretically be brought to rest through a single head-on collision with hydrogen (Glasstone and Edlund, 1952). The fewer collisions needed to moderate a fast neutron, the lower the fast neutron intensity will be. Elastic collisions with hydrogen and other light nuclei progressively moderate a fast neutron until it is either absorbed by a nucleus or is reduced to a velocity on the order of the thermal motions of surrounding molecules, at which point there is no net change in energy through subsequent collisions. A distinguishing characteristic of thermal neutrons is their strong tendency to be absorbed by nuclei. Common absorbing elements in the soil matrix include major elements such as Fe, Ca, K, and trace elements with unusually high absorption cross sections, such as B, Gd, and Sm.

Cosmic-ray neutrons

Cosmic-ray neutrons are an ever-present part of the land surface radiation environment. They are a by-product of chain reactions initiated at the top of the atmosphere by primary cosmic rays (Simpson, 1951) (A simulated particle cascade created by a 10 GeV primary interacting with nitrogen is shown in Figure 1). The primary radiation is composed of highly energetic particles, mainly protons and helium nuclei, which are believed to have been accelerated in shock waves associated with supernovas occurring throughout the Milky Way (Uchiyama et al., 2007). Energetic primaries collide with atmospheric gas molecules, unleashing cascades of secondary protons, neutrons, and other subatomic particles, some of which penetrate to sea level.

The neutrons utilized for passive water content measurements are generated mainly by cascade neutrons interacting with matter. Fast neutrons are produced in two types of interactions. A cascade neutron can transfer kinetic energy to an entire target nucleus, raising it to an excited energy state. The nucleus then cools off by “evaporation,” that is, the emission of fast neutrons in random directions. Cascade neutrons with higher energies will tend to interact at the surface of a nucleus, dislodging the outermost neutrons in a mostly forward direction (Krane, 1987). Regardless of how they are produced, fast neutrons

are scattered elastically in random directions until they are eventually absorbed by soil or atmospheric nuclei.

Fast neutron intensity at the land surface reflects the equilibrium between production, moderation, and absorption of neutrons in the ground and atmosphere (Figure 2).

Cosmic-Ray Hydrometeorology, Figure 1 Atmospheric particle cascade simulated with the radiation transport code Monte Carlo N-Particle eXtended (MCNPX – Pelowitz, 2005). A 10 GeV primary cosmic-ray proton collides with atmospheric nitrogen, triggering a particle cascade that reaches sea level. Fast neutrons are generated at each collision marked by a circle. The fast neutrons are scattered in random directions as they are moderated and eventually become captured.

Neutrons are scattered between the ground, which tends to be the better moderator when wet, and the atmosphere, which is the better thermal neutron absorber. Any change in water content at the land surface disturbs this equilibrium. An increase in the amount of soil water or snow decreases the intensity in the fast to epithermal region because neutrons are more efficiently reduced to lower energies through collisions with hydrogen. Conversely, thermal neutron intensity first increases with increasing water content and then decreases monotonically. This behavior is explained by the competing roles of hydrogen as an absorber and moderator. Initially, a small increase in water content rapidly increases the rate of thermalization, which increases the thermal neutron flux. But above a few percent gravimetric soil moisture content, the role of hydrogen as a moderator is challenged by its tendency to absorb neutrons.

Retrieval of soil moisture

For a wide range of soil compositions, a “universal” shape-defining function can be used to convert neutron counting rates to soil water content for typical silica-dominated soils (Figure 3). This function is valid for neutrons in the epithermal to fast part of the spectrum (10^0 – 10^6 eV), where neutron absorption is minor. A calibration curve for soil water content has been obtained by fitting simulated ground-level neutron fluxes to the semiempirical shape-defining equation:

$$\theta(\phi/\phi_r) = \frac{1}{B} \left(\frac{A}{(\phi/\phi_r) - D} - C \right) \quad (1)$$

where (ϕ/ϕ_r) is the neutron intensity normalized to a reference soil moisture state. The dependence of land surface neutron intensity in the epithermal to fast energy range on gravimetric soil water content is represented in

Cosmic-Ray Hydrometeorology, Figure 2 Depth profiles of neutron intensity near the land surface for different energies simulated with MCNPX. Between 10^1 and 10^6 eV, where elastic scattering interactions dominate, the shape of the profile and its sensitivity to soil moisture are remarkably constant. At lower energies ($<10^{-1}$ eV), thermal neutron absorption becomes important and the shape of the profile reflects the strong contrast between the absorbing properties of the ground and atmosphere. At higher energies ($>10^8$ eV) the profile reflects exponential attenuation expected for cascade neutrons.

Cosmic-Ray Hydrometeorology, Figure 3 The dependence of neutron intensity on soil water content at 0–2 m above the ground according to MCNPX calculations for a soil matrix with pure SiO_2 . For comparison, a curve for a pure CaCO_3 soil matrix is also shown.

silica-dominated soils by $A = 0.562$, $B = 0.060$, $C = 0.942$, $D = 0.449$, with the reference state dry soil. The shape of the function is not significantly altered by differences in soil texture, salinity, bulk density, or moderate amounts of carbonates or organic matter in soil.

Although the shape of the calibration function is largely invariant, the absolute “source” neutron intensity is highly variable across the surface of the Earth. In other words, the calibration function can translate on the intensity axis depending on location. Elevation differences are responsible for the biggest differences in source intensity. The elevation effect is more accurately described as a function of the mass shielding depth at a site, which is the product of atmospheric depth and air density and is expressed in units of g cm^{-2} . Local barometric pressure readings are usually an acceptable proxy for mass shielding depth. Neutron-generating cascades are attenuated exponentially as a function of mass shielding according to

$$\phi_2 = \phi_1 \exp[(x_1 - x_2)/\Lambda] \quad (2)$$

where ϕ_1 and ϕ_2 are the neutron intensities at depths x_1 and x_2 (g cm^{-2}) and the attenuation length Λ is $\sim 130 \text{ g cm}^{-2}$ at high to mid-latitudes (Desilets et al., 2006). According to this relationship, the neutron intensity at an elevation of 3,000 m (750 g cm^{-2}) is almost nine times greater than at sea level ($1,033 \text{ g cm}^{-2}$). Neutron intensity decreases by about half from high and mid-latitudes to the equator due to stronger magnetic shielding of primary cosmic rays at lower geomagnetic latitude. The elemental composition of soil may also have some effect on neutron source intensity because of differences

between elements in the number of neutrons emitted following excitation.

The spatial variability in cosmic-ray intensity means that the calibration function must be normalized to the local neutron source strength. This can be accomplished by obtaining at least one field calibration point. Because the radius of influence is large, many field samples are usually needed in order to obtain an areally representative average moisture (e.g., Western and Blöschl, 1999; Famiglietti et al., 2008). Different strategies to obtaining this point may be employed. One consideration is that average soil water content is ideally in the middle of the anticipated moisture range. Another consideration is that samples should be collected when the distribution of soil moisture is expected to be fairly uniform, in order to reduce the number of samples required for representativeness. A calibration is transferrable to another site if the topography, biomass concentration, and soil composition are similar between the two sites and elevations and latitudes are similar. Differences in source neutron intensity related to elevation and latitude can be compensated for by applying published scaling factors for neutron intensity (e.g., Desilets et al., 2006).

Counting rates should also be corrected for fluctuations in neutron source intensity over time. These are related mainly to variations in barometric pressure and solar activity. Corrections for barometric pressure can be made with Equation 2 using local pressure data and the local attenuation length for neutron-generating cosmic rays. Changes related to solar activity can be corrected using publicly available data from the global network of neutron monitors (Kuwabara et al., 2006).

Measuring neutron intensity

Neutron detectors tend to be most sensitive over a limited range of energies. The optimal sensitivity for soil moisture measurements is in the epithermal (10^0 – 10^1 eV) range because a reasonably high count rate can be achieved while sensitivity to neutron absorbers is minimized. Although the shape of the calibration function is nearly constant up to 10^6 eV, neutron intensity drops off rapidly with energy according to a $1/E$ law (Glasstone and Edlund, 1952). Measurements at higher energies therefore require larger or more efficient detectors or longer averaging times in order to compensate for lower neutron intensity.

The analytical precision of soil moisture determinations is governed by Poissonian statistics, which assumes that neutron counts are uncorrelated. The coefficient of variation is given by $N^{-0.5}$, where N is the counting rate. A precision of better than 2–3 % for 1 h of counting is easily achieved at sea level using portable equipment.

Sample volume

A major advantage of subaerial cosmic-ray measurements is that a large area can be sampled noninvasively from the ground or a low-flying aircraft. The radius of influence for 86 % (two e-fold drops) of the counts is 350 m at sea level

for a ground based, omnidirectionally sensitive neutron detector. Several factors are responsible for the large radius of influence: the neutron source is distributed across the land surface, the mean free path for atmospheric collisions is on the order of 30 m, and trajectories are randomized through collisions in the atmosphere. The footprint increases with elevation in proportion to the atmospheric collision mean free path length, which is inversely proportional to atmospheric pressure. The measurement depth depends strongly on soil moisture, ranging from 0.6 m in dry soil to 0.2 m in saturated soil for 86 % of the response.

Summary

Soil water content can be inferred from subaerial measurements of cosmic-ray neutron intensity. The hydrogen in soil water dominates the moderating power in the land surface environment. Through its ability to moderate and absorb neutrons, hydrogen exerts a strong control on neutron fluxes in the fast to thermal energy range. Cosmic-ray measurements are passive, noninvasive, noncontact, and represent a sample area of tens of hectares and a depth of tens of centimeters. The method has moderate power demands and data processing and transmission requirements, which makes it particularly well suited for long-term monitoring and field campaigns. A promising direction for future research is coupling neutron observations to land surface models and possibly even inverting neutron data to obtain soil properties and evapotranspiration. Furthermore, advances in neutron detection technology, for example, in the area of directionally sensitive neutron detectors (Mascarenhas et al., 2006), have the potential to open new applications and spatial scales for hydrologic measurements.

COST BENEFIT ASSESSMENT

Molly Macauley

Resources for the Future, Washington, DC, USA

Synonyms

Cost savings; Economic benefit; Net benefit; Societal benefit; Value of information

Definition

The “costs” of remote sensing usually refer to the direct monetary costs of designing, testing, constructing, deploying, operating, and maintaining the hardware (instruments, platforms, supporting infrastructure, communications networks) of remote sensing devices. These are typically the cameras, radar, lidar, or other instruments carried on aircraft or spacecraft for purposes of observing Earth processes (in situ remote sensing involves the hand-carrying of these devices). Costs also include the expenses of designing, testing, operating, and maintaining the software and other tools associated with using the data acquired from remote sensing instruments. Additional costs include those of personnel and may range from salaries of administrative and engineering experts to training and salaries of scientific researchers and the final “consumers” who use remote sensing for decision making. “Benefits” refer to the enhanced knowledge or scientific understanding gained from remote sensing as well as the practical applications which remote sensing data may contribute to. Benefits may be expressed in monetary measures or other quantitative measures such as “a percentage improvement in accuracy” or qualitative descriptions. “Cost benefit assessment” links costs and benefits in an attempt to measure the net gain from remote sensing – what benefits does it provide, after accounting for the costs incurred to glean those benefits?

Introduction

A decision whether to invest in remote sensing can be informed by understanding its costs and benefits. These costs and benefits are relevant to many decision makers, ranging from public officials who invest in remote sensing systems to consumers of information, such as managers of natural and environmental resources and the public at large.

Discussion

Costs

Although measuring the costs of remote sensing systems may be thought to be straightforward, accounting for all costs may be difficult in practice. The costs of hardware, software, and personnel may not be easily identified if they are included within broad categories in some cost accounting systems, making it difficult to assign costs specifically to a remote sensing system. For many users of remote sensing, data may be provided freely or at a marginal cost of reproduction, in which case costs as reported in budget statements may not represent the full cost to society of investment in a remote sensing system. In addition, the costs incurred to use remote sensing data may include common resources, such as shared computers, communications devices, and personnel, for which the allocation of cost among uses of shared facilities is difficult. In a study of how remote sensing data are transformed into information for managers of natural and environmental resources, such as national or local agencies or agricultural or geologic exploration companies, the National Research Council (NRC, 2001) identifies a range of indirect costs of transforming “data” into useful “information.” One of the conclusions of the NRC (p. 16) is that “transforming technical data into a form that is meaningful to nontechnical users – a process often including either the integration of remote sensing data with other types of data or scientific research to characterize the data (or both) – is highly dependent on the information requirements of applied users and on the skills of technical experts.” The NRC concludes that this process is poorly developed and an impediment – a cost – in effective use of remote sensing.

Benefits

Benefits of remote sensing include enhanced scientific understanding of the Earth and Earth processes, improved ability to make decisions in managing natural and environmental resources, and, arguably, the prestige accorded demonstration of technological prowess in building and deploying a remote sensing system or even the benefits to national or regional security associated with remote sensing of Earth resources. Benefits can accrue to the private sector as well as the public sector; in fact, some remote sensing systems are owned and operated exclusively by the private sector or as

joint arrangements between the private and public sectors.

The National Research Council (NRC, 2008) discusses the enhanced scientific understanding of the Earth and Earth processes from remote sensing. These accomplishments (benefits) include monitoring global [stratospheric ozone](#) depletion, detecting tropospheric ozone, measuring the Earth’s radiation budget, generating synoptic weather imagery, assimilating data for sophisticated numerical weather prediction, discovering the dynamics of ice sheet flows, detecting mesoscale variability of [ocean surface topography](#) and its importance in ocean mixing, observing the role of the ocean in climate variability, monitoring agricultural lands for a famine early warning system, and determining the Earth reference frame with unprecedented accuracy (see NRC, 2008, Table S.1, p. 4).

Numerous case studies have examined the benefits of applications of remote sensing for managing environmental and natural resources (for instance, see Battese, 1988; Ning, 1996; Nelson, 1997; Dudhani, 2006; Ward, 2000). Most of these studies express the benefits of remote sensing in terms of percentage improvements in statistical measures of accuracy; fewer studies express benefits in monetary terms. The primary difficulty in attempting to monetize benefits of remote sensing is that the environmental and natural resources themselves are typically “public goods,” that is, resources which, unlike ordinary goods and services, are not exchanged in markets (see Macauley, 2006 for a discussion of the challenges in valuing “information” such as remote sensing). Accordingly, it is difficult to ascribe monetary value to remote sensing data about nonmarketed resources. Bouma and coauthors (2009) carry out a case study of the value of satellite remote sensing of water quality in the North Sea and are able to monetize benefits in terms of the costs saved by water managers. Williamson and coauthors describe the economic value of remote sensing in improving forecasts of natural disasters in terms of reducing loss of life, property damage, and other costs. These approaches thus illustrate ways in which to express benefits in financial terms, but this line of research remains small and fragmented. And, because remote sensing data can often serve multiple purposes (remote sensing of land use, for instance, can inform highway planning as well as forecasts of agricultural production), a “unit” of data may be undervalued if only one of many applications of the data is evaluated in a case study.

Assessing costs and benefits

Few studies have attempted to assess the net benefits – that is, comparing both the costs and benefits of remote sensing and quantifying the extent to which benefits exceed costs. Given the difficulty in monetizing benefits, quantitatively relating benefits and costs is obviously even more difficult. In the few instances when benefits and costs are expressed in common units (say, dollars), the

comparison is easier. For example, if benefits are expressed in terms of costs saved, and if cost data are available, then benefits and costs can be compared (Bouma and coauthors make this comparison, for instance). If benefits and costs are combined, a general rule of thumb in benefit and cost assessment is that the *difference* between benefits and costs is preferred to the ratio between benefits and costs. Using the difference avoids the problem of whether a benefit is a negative cost, which can lead to ambiguous results when using the ratio rather than the numerical difference. (An example: In estimating the benefits of remote sensing in monitoring air pollution, is a reduction in pollution a benefit or an avoided cost? Expressing the reduction as a benefit or a cost will not affect the difference but will affect the result if benefits and costs are expressed as a ratio.)

Conclusion

Assessing the benefits and costs of remote sensing is one of the challenges of ascertaining the appropriate amount of investment a society should undertake in remote sensing systems. When is the cost of these systems justified by the benefits they confer? For a variety of reasons, quantifying costs and benefits is difficult. Expressing benefits in financial terms is particularly difficult, as remote sensing data may confer benefits in the form of new knowledge or about natural resources (air, water, climate, land, oceans) and the environment (air and water quality, land use). Society values these benefits, but ascribing monetary value to them is quite difficult.

Definitions

Crop stress. Crop response to environmental factors that results in suboptimal crop production.

Introduction

Crop stress is the plant response to environmental factors that ultimately results in suboptimal crop production. The environmental factors of primary interest to US corn, cotton, soybean, and wheat producers are water, nutrients, weeds, and insects. Not coincidentally, these are also the factors that are most easily managed through irrigation and applications of fertilizer, herbicides, and pesticides. Crops are generally managed to minimize crop stress within the constraints of producing a profitable yield and minimizing environmental impact. The day-to-day management decisions to achieve this delicate balance are based in part on information about the extent, duration, and cause of crop stress. The role of remote sensing in crop management is to provide such information about crop stress using sensors that acquire data in the visible (VIS), near-infrared (NIR), short-wave infrared (SWIR), thermal infrared (TIR), and synthetic aperture radar (SAR) wavelengths. A first step is to understand the physical plant manifestations associated with crop stress that are most easily detected with optical and microwave remote sensing.

Plant manifestations of crop stress

Water stress affects the plant leaf canopy by two primary mechanisms (Rosenthal et al., 1987). The first involves the closure of leaf stomata, which results in a reduction in

photosynthesis and transpiration. The associated increase in leaf temperature can be detected using remote sensing in the thermal infrared wavelengths (Jackson et al., 1981). The second mechanism involves a decrease in leaf expansion and an increase in leaf senescence. The reduction in plant leaf canopy development in comparison to well-watered plants can be detected through estimates of LAI or ground cover made using remote sensing in the visible wavelengths (Maas and Rajan, 2008). The mechanism affecting leaf stomata is initiated when available soil water in the root zone falls below 30 %. In contrast, the mechanism affecting leaf expansion and senescence is initiated when available soil water in the root zone falls below 50 %. Thus, leaf expansion and senescence typically are affected by water stress before photosynthesis and transpiration. There are a number of secondary effects of water stress that are associated with the adaptation of plants to the decrease in water availability.

The crop physiological adaptations to transient water deficit range from changes in canopy architecture to adjustments in leaf osmotic potential (Turner, 1977). Many of these adaptations have a pronounced effect on spectral reflectance and SAR backscatter and the optical properties of plants that allow stress detection with remote sensing. Crops have the capacity for developmental plasticity to complete the life cycle before serious water deficits develop. For example, studies have shown that wheat can hasten maturity in response to mild water deficits at the critical time between flowering and maturity. To endure prolonged water deficit while maintaining high water potential, some crops reduce water loss through increased epidermal waxes of leaves and a reduction in general plant productivity. Other adaptations are to reduce the radiation absorbed by the plant through leaf movement (e.g., leaf cupping, paraheliotropism, or wilting) or to reduce leaf area through decreased leaf expansion, reduced tillering and branching, and leaf shedding. It is generally reported that leaves under water stress show a decrease in reflectance in the NIR spectrum and a reduced red absorption in the chlorophyll active band (0.68 μm); however, Guyot et al. (1984) found that it was necessary to have an extremely severe water stress to affect the leaf reflective properties. In the TIR, there is a direct link between the process of plant water evaporation and the plant thermal response (i.e., water evaporates and cools the leaves) explained by Jackson et al. (1981).

Like crop water stress, crop nutrient stress has a direct effect on crop growth and development. Nitrogen is frequently the major limiting nutrient in agricultural soils. Leaves deficient in nitrogen absorb less and scatter more visible light (Schepers et al., 1996). Due to the link between leaf chlorophyll and nitrogen concentrations (Daughtry et al., 2000), leaves marginally deficient in nitrogen may appear a lighter, less saturated shade of green, and more severely nitrogen-stressed leaves may appear yellowish green and chlorotic. Thomas and Oerther (1972) found that with nitrogen deficiency, the visible reflectance increased (due to decreasing

chlorophyll content) and the NIR and SWIR reflectances decreased (due to decreasing number of cell layers). Nutrient deficiencies in crop canopies have the potential to affect canopy architecture and the optical properties of not only the leaf but also the stem and flower/grain head. Manifestations of typical nutrient stresses generally appear initially as changes in the optical properties of leaves and only later as change in the canopy architecture and decreased canopy biomass. The position of the red edge (an abrupt, step increase in the leaf reflectance in the NIR around 0.72 μm just outside the visible region) offers a robust metric for monitoring leaf and canopy nutrient status (Peñuelas and Filella, 1998). Recently, the concentration of epidermal polyphenolics, secondary metabolites in the leaf that may be measured using a commercially available clip-on UV absorption meter, has shown promise as a surrogate measure of leaf nitrogen status (see, for example, Tremblay et al., 2007; Demotes-Mainard et al., 2008; Meyer et al., 2006).

Crop stress due to weed interference has been attributed to many factors, including allelopathy and competition for sunlight, soil water, and nutrients (Sikkema and Dekker, 1987). The plant manifestation of weed-induced crop stress is generally reduced crop yields. Because weed distribution is influenced by drainage, topography, soil type, and microclimate, crop stress in weed-infested fields is highly variable. Variations in reflectance patterns and canopy temperatures over time and space may reveal crop stress associated with soil and topographic conditions (Wiles et al., 1992). In the early season, herbicide application is based simply on the presence or absence of plants, and remote sensing systems generally use the reflectance differences between relatively wide spectral bands in the visible and NIR spectra to make the distinction between plants and soil or rock (Medlin et al., 2000). Post-emergent herbicide applications require discrimination between weeds and crops, which is generally accomplished by using the difference between spectral signatures of crops and specific weeds or by acquiring images when weed coloring is particularly distinctive (Brown et al., 1994) or weed patches are comparatively large, dense, and/or tall (Pérez et al., 2000).

Remote sensing is not used to directly observe insects, but rather, to observe the damage to crop foliage and to detect plant canopy conditions that might be conducive to insect infestation. Early infestations of some insects are associated with leaf senescence or mortality, resulting in reduction in canopy density. Some crop pests not only cause physical damage to the leaf canopy but also cause a change in the spectral reflectance characteristics of the affected foliage. Aphids (*Aphididae*) deposit honeydew on cotton leaves which supports the growth of sooty mold (*Aspergillus* spp.), thus profoundly affected the reflectance characteristics of the leaves, particularly in the NIR (Maas, 1998). Other pests, such as spider mites (*Tetranychus* spp.), can cause changes in leaf reflectance that can be detected using remote sensing in the visible and NIR wavelengths (Fitzgerald et al., 2001, 2004). These spectral

signatures are distinct enough to differentiate them from water stress effects (Fitzgerald et al., 2000). Insects are sometimes attracted to areas within fields that contain the most vigorous plant growth. Areas of lush cotton growth in Louisiana were identified with spectral vegetation indices to direct scouting for the tarnished plant bug (*Lygus lineolaris*) and facilitate spatially variable insecticide applications (Willers et al., 2000).

Remote sensing of crop stress

Readers are referred to recent reviews by Moran et al. (2004) and Hatfield et al. (2004) for an extensive summary of remote sensing applications and products for detecting crop stress associated with water and nutrient deficiencies and weed and insect infestations. The greatest progress has been made in crop water stress detection. The use of remote sensing in irrigation scheduling has been reviewed by Maas (2003). Some spectral crop water stress indices have been commercialized for irrigation scheduling (Jackson et al., 1981; Burke et al., 1988). Opportunities for deriving crop nutrient status and pest infestation from remote sensing have recently increased with the development of hyperspectral and narrowband multispectral imaging sensors (Gitelson et al., 2006; LaCapra et al., 1996). The production of fine-resolution digital elevation models (DEM) with high vertical accuracies from radar systems provides useful supplemental information for the management of large agricultural areas. Recent development and launches of multispectral sensors with fine resolution has stimulated efforts to observe the early stages of pest infestations and areas with potential for pest infestations in time for control measures (Fitzgerald et al., 2004).

Conclusions

The technologies of the future will probably include sensors to measure natural and genetically induced fluorescence related to crop vigor (e.g., Liu et al., 1997), more focus on multispectral data fusion including SWIR, TIR, and microwave measurements (e.g., Jackson et al., 2004), and increased assimilation of remotely sensed data in crop yield models and decision support systems (e.g., Maas, 2005; Baez et al., 2005; Maas, 2005; Ko et al., 2005, 2006). The latter has the potential to address one of the greatest challenges to use of remote sensing as a source of information about crop stress – determining the cause of crop stress. It has been particularly difficult to discriminate crop stress due to water and nitrogen, which often produce similar plant manifestations but require different and costly management. Decision support systems based on crop growth theory can assimilate producer knowledge, management history, and remote sensing information to best determine the extent, magnitude, and cause of crop stress. This could lead to the turnkey solution called for by Hatfield et al. (2008) for application of remote sensing for agronomic decisions suited to both specialists and nonspecialists.

CRYOSPHERE AND POLAR REGION OBSERVING SYSTEM

Mark Drinkwater

Mission Science Division, European Space Agency,
 ESA/ESTEC, Noordwijk ZH, The Netherlands

Definition

Cryosphere. It collectively describes elements of the Earth system containing water in its frozen state and includes sea ice, lake and river ice, snow cover, solid precipitation, glaciers, ice caps, ice sheets, permafrost, and seasonally frozen ground. Although a significant portion of the world's snow and ice is found in the polar regions, cryosphere exists at all latitudes and in about 100 countries.

Polar regions. Earth's polar regions are the areas of the globe surrounding the north and south poles typically encompassed by a line of latitude corresponding to 66° 34' north or south (i.e., between each pole and its corresponding polar circle), which is the approximate limit of the midnight sun and the polar night. Alternatively, it can be defined as the region where the average temperature for the warmest month (July) is below 10 °C (50 °F).

Introduction

Knowledge of the state of the cryosphere is important for weather and climate prediction, assessment and prediction of [sea level rise](#), availability of freshwater resources, navigation, shipping, fishing, mineral resource exploration and exploitation, and in many other practical applications (IGOS, 2007). Changes to the cryosphere have far-reaching climate and socioeconomic consequences. The need for reliable global monitoring is essential to address the issues of climate and cryosphere within the Earth system. Despite its importance, the cryosphere remains one of

the most under-sampled domains in the Earth's climate system.

The *Cryosphere and Polar Region Observing System* (hereafter abbreviated as *CryOS*) shall provide a stable, long-term monitoring capability using a combination of in situ and remote sensing measurement capabilities (Drinkwater et al., 2008). The satellite remote sensing part of this system specifically fulfills the need for regular measurements of changes in the global cryosphere in response to climate variability and change. In particular, due to the logistical challenge of accessing the remote polar regions and high elevation cryosphere, together with the harsh weather conditions and extended winter-season darkness, satellites are the primary means of making year-round, day and night, weather-independent observations. Their advantage also lies in their ability to obtain uniform, consistent global sampling, including observations of the north and south polar ice-covered regions and lower-latitude mountain glaciers, permafrost, lake and river ice, and seasonally snow-covered areas.

The objectives of the satellite element of *CryOS* shall be to quantify snow- and ice-mass variability and mass, energy, freshwater, and gas exchanges between the cryosphere and the other elements of the Earth system (land, atmosphere, and ocean). This system element must respond to climate research and policy needs, socioeconomic needs, and operational snow and ice service needs. Moreover, the resulting data shall be made easily and freely available and shall be integrated with data from airborne and in situ observing systems for the purpose of developing a comprehensive record on cryospheric variability (Drinkwater et al., 2008, 2010).

Satellites contributing to *CryOS* must comprise a broad range of capabilities and have the ability both to sample the primary aspects of the cryosphere. Due to the sensitivity of the cryosphere to temperature and corresponding short timescales on which snow and ice may change, the system must be capable of providing global coverage with daily sampling from broad-swath, low-resolution sensors, complemented by high-resolution satellite sensors with the ability to provide detailed local and regional information, as required by the specific application.

Essential satellite elements of an observing system

The cryosphere and polar observing system must contain the following basic satellite capabilities:

- Daily, all-weather, global imaging
- High-resolution all-weather polar ice dynamics imaging
- Surface temperature and albedo change
- Ice topography/elevation/thickness change
- Gravity and mass distribution and exchange
- Position monitoring/navigation
- Telecommunications for data relay

Additionally, the geophysical products described in the list above require a source of independent measurement

data for product validation. Together these general capabilities are required to provide robust information on the main terrestrial and marine cryospheric domains.

Terrestrial cryosphere

For the terrestrial cryosphere, *CryOS* shall provide a complete picture of the snow reserves and solid precipitation, river and lake ice, permafrost, seasonally frozen ground, glaciers, ice caps, and ice sheets. This element of the observing system bridges meteorological and hydrological applications and ensures incorporation of data on the appropriate cryospheric variables in the next generation of hydrological and climate models. The basic challenge is to provide global data with the accuracy required for water management and disaster mitigation (e.g., avalanches), for monitoring climate change and variability, and for the estimation of [sea level rise](#).

Marine cryosphere

For the marine cryosphere, *CryOS* shall provide regular observations of sea ice and ice shelf characteristics and their dynamics. Ideally these data shall be supported by Global Ocean Observing System (GOOS) observations of ocean temperature, salinity, dynamic topography, and tides to understand the ocean-ice-atmosphere coupling processes responsible for variability and changes.

The following sections treat each of the cryospheric subdomains which require specific monitoring capabilities.

Snow extent and water equivalent

Terrestrial snow cover has the largest geographic extent of the components of the cryosphere covering nearly 50 million km² of the Northern Hemisphere in winter. Snow, with its high albedo, influences surface water and energy fluxes, atmospheric dynamics and weather, frozen ground and permafrost, biogeochemical fluxes, and ecosystem dynamics.

In order to support water, weather, and climate applications, various observations of snow are required. Remote sensing observations focus on the daily geographic extent of snow cover and snow water equivalent (SWE; the total water content) since these two quantities have a fundamental control on hydrologic and ecosystem processes.

Point measurements of solid precipitation and snow depth on the ground are often unrepresentative of surrounding areas, and so satellite remote sensing data must be combined with these snow measurement sites to provide a consistent picture at regional or continental scale. Satellite measurements of snow extent are typically accomplished using visible and near-infrared sensors on satellites in either polar low Earth orbit (LEO) or geostationary orbit (GEO). Using such multispectral measurements from GOES, MSG/SEVIRI, AVHRR, MODIS, MERIS, MISR, and AATSR, it is possible to discriminate between snow- and cloud-covered regions and to establish

the extent of snow cover. Currently, these sensor data are complemented by all-weather SWE products produced from passive and active microwave data with appropriate frequencies such as SSM/I, AMSR-E, and ASCAT; QuikSCAT; and Oceansat-2 Scat though their low spatial resolution currently limits their use in hydrometeorological models. Future multiple-frequency (Ku- and X-band), high-resolution active microwave sensors such as synthetic aperture radars (SAR) (see entry [Data Processing, SAR Sensors](#)) must be developed specifically for measurement of SWE at the relevant sub-kilometer scale.

Solid precipitation

To date satellite precipitation measurements have greatly increased our ability to monitor and observe liquid precipitation (i.e., rainfall) globally. However, a similar capability does not yet exist at high latitudes for solid precipitation (i.e., snow and hail). Thus, development of a robust snowfall measurement capability remains a high priority for the cryosphere, such that the contribution of this critical element of the high-latitude water cycle can be fully characterized.

River and lake ice

Lake and river ice are a key component of the terrestrial cryosphere, and seasonal ice growth plays an important role in regulating physical, chemical, and biological processes. Long lake and river ice records serve as an indicator of high-latitude climate variability and serve as an important data source for initializing weather forecast and climate models (Jeffries et al., [in press](#)). Meanwhile, the presence of freshwater ice also has a number of socioeconomic implications ranging from transportation to the occurrence and damaging effects of ice-jam flooding.

The observing system must be able to monitor the seasonal distribution and duration of lake and river ice. Autumn freeze-up and spring time thaw may be monitored at high resolution (10–120 m) under daylight conditions using Landsat MSS or TM and SPOT HRV for small lakes and narrow rivers, whereas for larger features the detection of the presence of ice has more traditionally been accomplished using medium-resolution (250 m–1 km) visible and infrared AVHRR and MODIS products. Nonetheless, extensive cloud cover and periods of darkness in winter limit their use at high latitudes. For establishing freeze-up and break-up dates and for year-round monitoring of seasonal ice on smaller lakes and rivers, SAR image products from ERS-1 and ERS-2, RADARSAT-1 and RADARSAT-2, Envisat ASAR, ALOS PALSAR, and TerraSAR-X may be considered more optimal (Jeffries et al., [2005](#)). These are complemented by scatterometer and passive microwave monitoring of the largest lakes.

Permafrost

Permafrost is subsurface soil which remains at or below the freezing point of water for 2 or more years.

Such permanently frozen ground and seasonally or intermittently frozen ground is widespread in the Arctic, subarctic, alpine, and high plateau regions, and in ice-free areas of the Antarctic and subantarctic. In the Northern Hemisphere, permafrost is estimated to cover approximately 23 million km² with up to 17 million km² of this underlying exposed land (Brown et al., [1997](#)). Seasonal and intermittently frozen ground together occupies approximately 56 million km² in the Northern Hemisphere and includes the “active layer” over permafrost (i.e., the layer which undergoes seasonal thawing) and soils outside permafrost regions (Zhang et al., [2003](#)).

Permafrost and the freeze-thaw state of land surfaces exert a critical influence on the surface energy balance, hydrologic cycle, ecosystems, biogeochemical fluxes, hydrology, and weather and climate systems. Further, permafrost thaw can have significant socioeconomic consequences through its direct impact on structures such as roads, buildings, railways, and pipelines.

The primary needs in permafrost areas are to determine the terrain and its changes over time (including topography and vegetation characteristics), in association with the thermal state of the surface. Near surface soil freeze-thaw state is a critical variable since it is a primary indicator in relation to the fluxes of energy, water, and carbon. Unlike other components of the terrestrial cryosphere, subsurface properties of permafrost terrain are not directly observable from remote sensing platforms. However, many surface features of permafrost terrain are observable with a variety of sensors ranging from aerial photography and high-resolution optical satellite imagery to synthetic aperture radar and satellite passive microwave radiometry (Duguay et al., [2005](#); Kääb, [2008](#)).

Passive optical imaging radiometers operating at visible and infrared wavelengths have traditionally been used under cloud-free conditions to map changes in the characteristics and thermal condition of permafrost terrain. Very-high-resolution (0.2–5 m pixels), narrow swath optical sensors such as EO1 Hyperion, Ikonos, or QuickBird can provide extremely detailed information on small features of the landscape. For mapping the evolution of features over time, ASTER, ALOS PRISM, ALOS AVNIR-2, and SPOT image data (10–100 m pixels) can be used, with the advantage of availability of SPOT data since the mid-1980s. For large area land cover mapping, these are complemented by medium-resolution (250 m–1 km pixels) broader swath imaging instruments (such as MERIS, MODIS) providing regional to continental scale coverage on a daily basis. Low-resolution (12–25 km pixels) image data from passive microwave radiometers and scatterometers, for example, have the advantage of year-round, daily, weather-independent continental scale coverage, and may be used to monitor the circumpolar spatial and temporal details of freeze and thaw cycles.

In addition, digital terrain models (DTMs) are also essential for understanding and modeling permafrost and

its evolution. High-resolution and high vertical accuracy DTMs may be derived at high-latitude tundra permafrost from repeat-pass InSAR or tandem interferometry (i.e., ERS-2-Envisat ASAR cross interferometry, COSMO-SkyMed, or TanDEM-X) measurements. Meanwhile changes in permafrost terrain may be detected using differential InSAR or DInSAR (i.e., the calculation of ground deformation from the difference between two InSAR images). In addition to InSAR techniques, lower-precision optical DTMs can be derived from stereoscopic optical sensors, such as SPOT HRV, Cartosat-1, and ALOS PRISM, or using stereophotogrammetry.

Ice sheets (topographic change, mass change, and sea level)

Ice sheets play a key role in the climate system, locking up vast amounts of freshwater in the form of snow and solid ice, and by their significant influence on the energy balance of the polar regions. The two major ice sheets remaining from the last ice age blanket most of Greenland and Antarctica. They contain enough freshwater, in the form of ice, to raise sea level by approximately 7.2 and 62 m, respectively (Alley et al., 2005). The inland ice rests on bedrock, while their floating ice shelf extensions link the ice sheet with the ocean. Ice is transported from the inland toward the ice shelves via fast-flowing ice streams and outlet glaciers.

Ice sheets undergo seasonal growth by snowfall and then wasting by summer melting, with accompanying release of freshwater into the ocean. The extent to which ice sheets and glaciers are changing is reported as “mass balance” by measuring the net inputs and net losses. The totals of precipitation and accumulation, ablation, melting, runoff, sublimation/evaporation, ice dynamics, and iceberg calving are reported over the course of each year and used to compute the net balance either as a gain in mass (positive) or negative loss of mass (negative). Ice sheets may lose mass by a combination of dynamical processes which govern ice stream flow across the grounding line, or by surface ablation, basal melting, and iceberg calving at the seaward margins of floating ice shelves. Exchange of mass between ice sheets and oceans as freshwater has a major impact on both ocean circulation and sea level and is currently estimated to contribute more than 0.3 mm/year (30 cm/century) to sea level.

Since the early 1990s, there are indications that rapid changes are taking place particularly around the margins of the Greenland and Antarctic ice sheets (Rignot et al., 2008; Van Den Broeke et al., 2009). A combination of remote sensing methods have highlighted that streaming ice flow (i.e., ice motion) is responsible for the largest proportion of mass loss from the ice sheets. By contrast, the central plateau of both ice sheets appears to be close to net neutral balance, with accumulation balancing ice-mass losses.

Remote sensing of ice sheet behavior relies on the ability of the sensors to acquire data over vast areas of terrain,

during day or night and also in all-weather conditions. Optical satellite data at visible wavelengths have been used since the 1960s to define changes in the ice margin and surface characteristics, with pairs of images acquired at different times used for motion of the surface and digital terrain model generation, the latter in stereographic mode.

Passive microwave radiometer or scatterometer images of ice sheets are often used to measure the onset, duration, and extent of ice sheet surface melt, since they are sensitive to the appearance of melt water in snow. Each has also been used to make estimates of mean annual snow accumulation.

Changes in ice sheet surface elevation averaged over large areas can be interpreted as a measure of changing ice sheet volume. Since 1978, successive radar altimeters have measured ice sheet and ice shelf surface elevation. Their primary limitation has been their ability to recover accurate data in the steep terrain around the edges of the ice sheets. Recently, this limitation has been addressed with the CryoSat-2 SAR interferometric radar altimeter. The ICESat laser altimeter has also recently acquired detailed topography around the sloping margins of the Greenland and Antarctic ice sheets. The advantage of the laser altimeter is its smaller measurement spot on the surface, allowing more accurate elevation data, albeit limited by optically thick cloud conditions.

SAR measurements complement the other remote sensing instrument data described above, through high-resolution observations. Since the early 1990s, SAR images have provided a wealth of new information on characteristics of the ice sheet surface, though the advent of SAR interferometry (InSAR) has enabled measurement of details of topography as well as precise details on the motion of ice (Rignot et al., 2011). In conjunction with ice sheet models, InSAR data provide a valuable means to study the impact of ice stream velocity on the net loss of ice mass.

Satellite gravity provides direct measurements of gravity anomalies due to ice sheet mass unloading or ice sheet mass change. Data from the GRACE satellite confirms other measurements which suggest that the Greenland and Antarctic ice sheets are losing mass around their margins over the last decade (Rignot et al., 2008; Van den Broeke et al., 2009). The high-resolution geoid and gravity anomaly data acquired by the GOCE satellite will serve as a precise reference for elevation changes and to understand the details of gravity anomalies due to isostatic adjustments to ice-mass unloading.

The observing system for quantifying ice sheet and glacier changes and their contribution to sea level include a number of contributing measurement capabilities (Wilson et al., 2010). Continued surveys by satellite radar and laser altimeters are needed to provide elevation changes over broad areas on a routine basis. These should ideally be coupled with continued time series of interferometric synthetic aperture radar (InSAR) measurements of glacier velocities to understand changes in ice thickness due to ice discharge. In addition, time series of satellite

gravimetric measurements of the static and time-varying components of the gravity field reveal net ice-mass changes over large regions and entire ice sheets. Periodic surveys by optical systems may also be beneficial as another means of mapping of changes in ice stream margins, ice shelves, or for complementary Digital Elevation Model generation.

Sea ice extent and concentration

A significant fraction of the surface of the world's polar ocean is frozen at any given time. Sea ice grows seasonally from 7 to 16×10^6 km² in the Northern Hemisphere and from 3 to 19×10^6 km² in the Southern Hemisphere, covering up to about 10 % of the surface area of each hemisphere at the respective winter peak. Arctic sea ice observations over the last 30 years indicate significant decreases in total area and extent of sea ice, although regional patterns of change can be highly variable and indicate opposing patterns of growth or decay in extent on interannual to decadal timescales.

Polar sea ice has an important climate regulating impact by limiting exchanges of momentum, heat, and moisture between the ocean and atmosphere. Due to the large difference in albedo between ice and ocean, reductions in sea ice extent by melting result in more heat being absorbed by the ocean, thereby amplifying the effects of high-latitude warming. Sea ice redistributes salt and freshwater by rejecting brine when it freezes, transporting freshwater by ice drift, and ultimately by depositing this freshwater in the upper ocean during summer melt. Thus sea ice variability exerts a considerable impact on the regional energy and freshwater budgets, as well as directly impacting the temperature, salinity, and buoyancy of brine in the upper ocean.

Daily observations of sea ice extent and concentration (fractional coverage of ice in a given area) are required to understand the thermodynamic evolution of the sea ice cover on seasonal to interannual timescales (Breivik et al., 2010). Satellite passive microwave radiometer observations (from ESMR, SMMR, SSM/I, and AMSR-E) have traditionally been used for this purpose as they are capable of daily mapping of the entire sea ice cover of both polar regions. The 30 year continuous time series of dual-polarized, multifrequency passive microwave radiometer data spanning the period from 1979 until the present day (Cavalieri et al., 1996; Comiso et al., 2003) has become the backbone of the sea ice monitoring system (see <http://www.nsidc.org/seaice/>). More recently, radar scatterometer images have been used to complement these radiometer data (Long et al., 2001). Their combination helps to distinguish between seasonal and perennial, or multiyear, ice and to provide more robust information on ice conditions during surface melting conditions. This synergy allows more robust retrieval of sea ice characteristics in operational sea ice products (e.g., EUMETSAT sea ice products: <http://saf.met.no/p/ice>).

Daily passive microwave radiometer observations have been supplemented by continuous visible and infrared very-high-resolution radiometer (1 km pixels) data since the 1970s with the NOAA AVHRR instrument series and DMSP OLS. More recently, the NASA Moderate Resolution Imaging Spectroradiometer (MODIS) added to this capability. During cloud-free, sunlit periods, this class of sensors provides supplemental information on ice concentration and ice characteristics such as albedo and thickness from reflective characteristics. During the cold season, cloud-free infrared data may also be used to derive ice surface temperature using a split-window technique which employs two thermal bands (typically at 11 and 12 μ m).

The advent of SAR has revolutionized the capability to study sea ice at much higher resolution. Since the early 1990s, SAR has provided detailed images of sea ice at spatial resolutions of up to 30 m, including information fracture or lead locations/orientations with relatively thin ice, and information on ice ridging with relatively thicker, deformed ice. Wide-swath SAR (up to 500 km wide swath) has added the capability to deliver synoptic-scale coverage (up to 1,000 km) on timescales of 1–3 days, with complete Arctic coverage on a weekly basis (Kwok et al., 1999).

Sea ice thickness and dynamics

In order to fully appreciate the variability in sea ice mass and volume in response to climate variability, it is also required to measure sea ice thickness and drift dynamics. Both variables are essential to partition the role of thermodynamic and dynamic contributions to ice thickness changes, or to quantify advective fluxes of freshwater in the form of ice.

Ice drift data are derived from image pairs of the same region typically spaced at intervals of one to several days, using a variety of computer tracking algorithms which measure displacement of ice features over time. Daily passive microwave radiometer and scatterometer products have been used as a basis for Arctic and Antarctic ice drift products (Breivik et al., 2010), with merging of the drift fields from these two instruments providing more reliable results over several day intervals (Laverne et al., 2010). Notably, the accuracy of these products is limited by the resolution of the sensor and the intervals between images, which prevents the details of ice drift to be recorded on short time (<2 days) and space (<10 km grid) scales. For this purpose wide-swath SAR data from RADARSAT and Envisat ASAR have been used to estimate ice drift on a much finer grid, limited only by the image resolution and pixel spacing of 100–150 m. Using consistent time series of such products, it is possible to resolve the details of ice drift velocity and divergence and convergence of the ice, together with the dynamical thickening and drift-related area flux of sea ice (Kwok, 2011).

Since data from active and passive microwave imaging sensors do not contain sea ice thickness information

content, it was necessary to develop this capability. Radar altimeter measurements of ice surface elevation or freeboard (i.e., the difference in elevation between the ice surface and sea level in leads), together with ice density and snow-loading information, allow conversion of freeboard to ice thickness along profiles across the ice surface. Both the ICESat lidar and CryoSat-2 radar altimeter missions, with their higher resolution and measurement precision, allow changes in thickness and volume of sea ice to be estimated over sea ice cover.

The final goal of combination of sea ice thickness, concentration, and dynamics data is to make a complete estimation of ice volume fluxes (Kwok et al., 2009; Kwok, 2011). Using time series of each of these quantities, it becomes possible to estimate the seasonal to interannual variability in ice fluxes and, thus, the variability in transport of freshwater from high to lower latitudes.

With the future combination of passive microwave radiometers such as SSM/I and JPSS/MIS, and C-band SAR such as RADARSAT-2 and RADARSAT-3, and GMES Sentinel-1, and SAR altimeters such as CryoSat-2 and GMES Sentinel-3, a robust sea ice observing system component is assured for the next decade or so.

Albedo and surface temperature measurements

Observations of broadband albedo and surface temperature are required for characterizing surface-atmosphere radiation budgets and energy exchanges over polar snow, ice, land, and ocean surfaces. Albedo varies considerably for different snow and ice surface properties (from 35 % to 95 %), and changes dramatically with snow metamorphism due to temperature variability or melting, or underlying surface properties (Perovich et al., 2002). Broadband albedo measurements are accomplished by passive, multi-angle optical measurements in the visible and shortwave-infrared spectral range.

Surface temperature of snow, ice, ocean, or frozen ground is also important for the determination of energy exchanges and for understanding onset of processes such as snow metamorphism or freeze and thaw. Accurate temperature observations help constrain surface radiative and turbulent fluxes, and can help improve water and energy budgets for the cryosphere.

To date these measurements have been accomplished by passive visible and infrared radiometers operating in the visible and infrared range such as AVHRR, ASTER, ATSR, AATSR, MODIS, MISR, and MERIS instruments, with the future continuity in measurements secured with the future GMES Sentinel-3 OLCI and SLSTR instruments, and the NPP and JPSS VIIRS instrument successors to MODIS.

Gravity and the geoid

The measurement of small spatial and temporal variations in the Earth's gravity and of the geoid (i.e., equipotential reference surface) are required to quantify snow- and ice-mass distribution and mass transports including

freshwater exchange between land, ocean, ice, and atmosphere and for constraining heat, energy, and freshwater cycling through the Earth system.

Since 2000, three missions have contributed valuable data to meet these needs. The CHAMP, GRACE, and GOCE satellites have sequentially improved knowledge of the static gravity and geoid, while GRACE has revolutionized our understanding of the time-variable component of the gravity field. The GOCE mission promises to deliver a revolutionary accuracy in the static geoid over its operating lifetime. Gravity gradients from its fundamentally new gradiometer instrument, coupled with precise orbit information, give access to approximately 2 cm geoid accuracy at 100 km spatial resolution. This geoid promises a uniform global reference level for altimeter detection of regional dynamic ocean topography or sub-centimeter eustatic sea level changes (see entry [Sea Level Rise](#)) (over a nominal satellite lifetime of several years) in response to ice sheet melting (Wilson et al., 2010).

The GRACE follow-on (GRACE-FO) mission, currently being prepared for launch in 2016, is designed to provide a gap-free succession of data between the current GRACE mission and an upgraded GRACE-II planned for launch in the 2020 timeframe. GRACE-FO will continue to map the Earth's gravitational field with regional resolution and monthly variability.

Other infrastructure considerations

For the polar and cryospheric observing system to fulfill all essential needs, it is necessary to consider also a number of other critical issues which indirectly require other satellite remote sensing capabilities.

Ground-based observations

As opposed to remote sensing measurements, in situ measurements are made in direct contact with the medium of interest and typically result in sparse or sporadic observations in space or time (i.e., by comparison to the satellite data). Independent in situ, surface-based measurements of known quality of the physical state of the relevant cryospheric subdomain, or atmosphere, land, or ocean are required to understand the physical processes at work and to validate the satellite data products. Reference observation networks of autonomous or manned stations are needed for this purpose. Capabilities include precipitation (solid/liquid); snow water equivalent; vertical profiles of temperature, physical, and dielectric properties; satellite-tracked buoys (ice/ocean); automatic weather stations; and glacier or ice sheet GNSS survey reference sites.

Satellite communications and positioning

Operations in the polar regions and particular navigation in sea ice require a combination of satellite-based communications and accurate positioning. Many in situ observing measurement systems rely on some combination of

positioning, and satellite communications/data relay to operate successfully (e.g., autonomous drifting buoys).

Communications satellites are invaluable to telecommunications uses such as data relay in the polar regions. Modern communications satellites use a variety of orbits including geostationary orbits, elliptical (e.g., Molniya) orbits, and other and low (polar and nonpolar) Earth orbits. Communications satellites provide a microwave-based radio relay capability which today is used extensively for mobile applications such as communications to ships, aircraft, and handheld terminals, for which, in polar regions, alternative technologies do not exist. New highly elliptical orbiting polar communications and weather satellite systems such as the Canadian Polar Communications and Weather (PCW) and Russian Arktika satellites are currently in development to improve monitoring capability and high-latitude activities.

Today, accurate navigation and positioning has become dependent on satellite aids such as satellite navigation or Global Navigation Satellite Systems (GNSS) such as the currently operational US Global Positioning System (GPS) and the developing European GALILEO, the Russian GLONASS, and the Chinese BeiDou-2 (or COMPASS) systems.

Measurement reference frames

An accurate and stable measurement reference frame is essential for most precise remote sensing measurement techniques such as the altimetry and InSAR techniques discussed earlier (Wilson et al., 2010). This requires the following:

- Sustained support for satellite remote sensing tools integral to the International Terrestrial Reference Frame (ITRF), including satellite laser ranging, very-long-baseline interferometry, DORIS, and GNSS
- Inclusion of observations of the static gravity field from GOCE and other stand-alone missions to determine a precise, high spatial resolution geoid
- ITRF accurate to approximately 1 mm and stable to approximately 0.1 mm/year or better, in order to be able to understand the consequences of a changing cryosphere upon the rate of sea level change

Remote sensing product validation

One of the shortcomings in cryospheric remote sensing measurements is that algorithms used to retrieve geophysical data products may be sensitive to spatial variability, topography, atmospheric propagation, or other diurnally or seasonally driven physical effects. To check the robustness of measurements and veracity of the resulting products over time, it is necessary to perform product validation.

Independent validation measurement data are typically acquired during in situ experiments synchronized with the satellite overpass times, at specific carefully selected instrumented sites. In situ measurements must also be made at the appropriate time and space scale for

effective comparison with the satellite sampling. Comparison of well-calibrated in situ measurements with the satellite data products allows the evaluation of the consistency of measurements over time, and for the sources of uncertainties and biases in the satellite data to be rigorously quantified.

Validation of cryospheric products also relies on critical ancillary data provided by existing in situ measurement networks which report regularly via the Global Telecommunications System (GTS) or other satellite communication links. These networks include buoys in the ocean and sea ice pack, Global Observing System (GOS) weather stations and snow cover monitoring sites, and other terrestrial network sites comprising the Global Terrestrial Networks for Permafrost (GTN-P) and Glaciers (GTN-G).

Summary

Due to the complex interrelationships between the terrestrial, alpine, and marine elements of the cryosphere, the space component of the cryospheric and polar region observing system (*CryOS*) is needed to provide comprehensive information on all cryospheric domains. Methods of remotely sensed observations may be common to these domains, and thus the principal challenge for *CryOS* is to identify ways to develop, coordinate, maintain, and sustain these remote sensing observations within the GEOSS framework (Drinkwater et al., 2008; Jezek and Drinkwater, 2010).

Notably, the cryospheric and polar region observing system is recognized to require more than remote sensing measurements of snow and ice properties from satellites or airborne platforms. It must also include complementary networks of ground-based instrumentation as well as other capabilities such as modeling, data assimilation, and reanalysis systems and comprehensive data archiving and management systems.

CRYOSPHERE, CLIMATE CHANGE EFFECTS

Aixue Hu
 Climate and Global Dynamics Division, National Center
 for Atmospheric Research, Boulder, CO, USA

Synonyms

Frozen water sphere; Solid water sphere

Definition

The cryosphere is defined as the part of the earth's surface where the water is in solid form. It includes the sea ice, lake and river ice, glaciers and mountain ice caps, ice sheets, snow cover, and the frozen ground (including permafrost). The cryosphere is important to global climate due to its high reflectivity (albedo) of the sun's rays. Changes in the cryosphere affect the global heat balance and thus modulate the global climate.

Albedo is the reflectivity of the earth's surface to the incoming solar radiation (sunlight).

Introduction

The cryosphere is an integral part of the earth's climate system. It is closely linked to the earth's surface energy budget, the water cycle, sea level changes, and the surface gas exchanges. Presently, the cryosphere on land contains about 75 % of the world's freshwater, mostly in the Greenland ice sheet and the Antarctic ice sheet. The total melt of these two ice sheets would increase the global sea level by about 64 m. In the past million years, the cryosphere has gone through significant changes on different time scales, such as the Ice Age. When the global climate cools, the cryosphere expands, and when the global climate warms, the cryosphere shrinks. On the other hand, the cryosphere not only responds passively to changes in the global climate, it also actively modifies the global climate through the albedo feedback. In general, roughly 80–90 % of the sun's rays reaching the snow or ice surface are reflected back into space. In contrast, only 10 % of the sun's rays are reflected back to space from the ocean surface. In a colder climate, the growth of sea ice and the snow cover and ice sheets on land would increase the albedo, which reflects more of the sun's rays back into space and reduces the heat absorption by the earth's climate system, leading to a further cooling effect of the climate. In a warmer climate, the shrinkage of the cryosphere would reduce the global albedo, thus allowing more of the sun's rays to be absorbed by the earth's climate system and make the climate even warmer. This is a positive feedback.

Present state of the cryosphere

Mean state of the cryosphere

Currently, about 10 % of the earth's land area is covered by ice, mostly in the Antarctic and Greenland; only a tiny fraction lies in the ice caps and mountain glaciers. In the annual mean, sea ice covers about 7 % of the earth's ocean area. In the Northern Hemisphere, the maximum sea ice extent is about 15 million square kilometers in winter, with a minimum of about 3.6 million square kilometers in summer in the Arctic and the adjacent seas. In the Southern Hemisphere, the sea ice covers about 19 million square kilometers of ocean in winter and about 3 million square kilometers in summer. In the Northern Hemisphere winter

season, snow covers about 33 % of the land north of the equator and reaches 49 % in midwinter. Since the land area south of 40 °S is very small in the Southern Hemisphere, the region with snow cover in winter is small, except for Antarctica. The frozen ground (including both seasonally frozen ground and permafrost) covers about 51 % of the land area in the Northern Hemisphere in winter, of which about half is permafrost.

Changes of the cryosphere during the twentieth century

Based on both historical and satellite observations, the snow cover has declined in spring and summer in the Northern Hemisphere since the early 1920s, especially since the late 1970s, but the changes are small in winter (Lemke et al., 2007). In the Southern Hemisphere, little or no long-term trend is found from the satellite observations for the last three decades, but there is substantial interannual variability.

For the river and lake ice, studies show that the freeze-up date in the late fall is later, with a rate of change of 5.8 ± 1.6 days per century, and the break-up date is earlier, changing at a rate of 6.5 ± 1.2 days per century for selected rivers and lakes in the Northern Hemisphere (Magnuson et al., 2000).

In terms of sea ice, the satellite observations show a significant declining trend (-7.4 ± 2.4 % per decade from 1979 to 2005) for the Northern Hemisphere summer sea ice extent (Comiso, 2003). The 2012 summer minimum sea ice extent was only about 3.6 million square kilometers, a dramatic reduction in comparison to the 1979–2000 average minimum of about seven million square kilometers. The winter sea ice cover is also shrinking in the Northern Hemisphere with a rate of about 44,000 km² per year since 1979. In the Southern Hemisphere, the sea ice cover increased slightly during the recent decade, but it is not statistically significant. On the other hand, from up-looking sonars on submarines and some moored instruments that measure sea ice thickness, a drastic thinning of the Arctic multiyear sea ice around the late 1980s is found (Johannessen et al., 2004). There is no trend before the late 1980s (Tucker et al., 2001).

The glaciers and ice caps which are not adjacent to the large ice sheets of Greenland and Antarctic occupy only a very small portion of the land surface. However, these glaciers and ice caps affect the river runoff since most of the large rivers originate there. Variations of the stability of these glaciers and ice caps would affect the river flow in spring and late summer. Studies show that the retreat of the glaciers and ice caps became evident globally as early as 1850 (Oerlemans, 2005). Regionally, the retreat of the glaciers and ice caps has been significant everywhere except in Europe and the Andes since 1960s (Dyurgerov and Meier, 2005). In Europe and the Andes, the glaciers and ice caps show evidence of retreat since the 1990s.

Since the Greenland and Antarctic ice sheets hold huge amounts of ice which could significantly raise the sea level if they were to fully melt, it is important to monitor the changes in the ice sheets and study the impact of these ice sheets on global climate in the future. In the Greenland ice sheets, about half of the ice loss is by surface melting and runoff into the sea. In the Antarctic, ice is drained by slow-moving ice at the center of the ice sheet and by faster-moving ice-walled ice streams or ice shelves and narrow ice tongues at the edges. Observations from multiple sources, including from remote sensing instruments, show that the Greenland ice sheet mass was balanced during most parts of the twentieth century, but the Greenland ice sheet started to lose mass since the early 1990s with an accelerating trend (Lemke et al., 2007). In the Antarctic, the ice sheet appears to be losing mass all the time which might be associated to the past forcing since portions of the ice sheet respond very slowly. Recent satellite observations indicate that there is a slight mass gain in the eastern Antarctic and a more significant mass loss in the west Antarctic (Rignot and Thomas, 2002; Zwally et al., 2006). The total contribution of the ice sheets, glaciers, and ice caps to the [sea level rise](#) has been about 1.2 ± 0.4 mm/year from 1993 to 2003.

Observations show a warming of the permafrost all over the world in the twentieth century, especially in the late twentieth century when data are more abundant (Lemke et al., 2007). In some regions, this warming causes the permafrost to degrade. The degradation of the permafrost can cause significant problems for human activities. Thawing can induce the subsidence of the ground, a downward displacement of the surface, especially for the ice-rich permafrost. Typically, this subsidence does not happen uniformly; some regions would rise up and some regions would sink. Any man-made infrastructure standing on the thawing permafrost can be significantly damaged. On the coast of the Arctic, the permafrost degradation causes an erosion of the coastline by up to 3 m per year. For the seasonally frozen ground, the active layer which thaws and freezes on top of the permafrost becomes thicker, indicating a downward propagation of the surface warming signal. The area of the seasonally frozen ground outside of the permafrost region has shrunk about 7 % in the Northern Hemisphere during the last century.

The cryosphere in past climates

In the past million years, the earth's climate has experienced a few cold-warm cycles – the glacial-interglacial cycle. Each of these cycles lasted about 100,000 years. The most recent interglacial started about 10,000 years ago. The cause of these glacial-interglacial cycles is not well understood, but strong evidence indicates that these are linked to regular variations of the earth's orbit around the sun, the so-called Milankovitch cycles. In each of these cycles, the amount of the solar radiation reaching the earth surface changes at each latitude in each season,

but may not change the annual mean value. Many studies suggest that the total amount of solar radiation reaching the North Hemisphere in summer is crucial for the starts and ends of this climate change cycle. If the snow in the previous winter can survive the following summer, snow cover would grow and ice sheets would grow due to the albedo feedback. A growing ice and snow cover on the earth's surface would reflect more sunlight into space and further cool the earth's climate, the ice sheets grow bigger, the glaciers and ice caps grow towards lower altitudes, and sea ice cover expands towards the equator. At the last glacial maximum (about 21,000 years before present), the global sea level dropped by about 120 m, or about 120 m of shallow ocean was turned onto land. The ice sheets covered a significant portion of the North America continent up to 45°N (called the Laurentide ice sheet), a large portion of Europe, and part of the western and middle Russia (called the Weichselian ice sheet) in the Northern Hemisphere and southern South America (called Patagonian ice sheet) and the Antarctic in the Southern Hemisphere. These ice sheets were, in general, about 3–4 km thick.

Projected changes of cryosphere in future climate

In the recent report of the Intergovernmental Panel on Climate Change (IPCC, 2007), scientists using comprehensive state-of-the-art coupled climate models show that the status of the sea ice cover, snow cover, and frozen ground in the future climate depends heavily on how much CO₂ is emitted into the atmosphere by human activities. The Arctic could be seasonally ice-free in the mid-to-late twenty-first century if the CO₂ emission were high (Meehl et al., 2007). If so, human and marine life would be affected dramatically. Polar bears rely on the sea ice to hunt for food. If there is no sea ice at all in summer, polar bears would not be able to obtain enough nourishment. Model projections also show a significant reduction of the snow cover in the Northern Hemisphere, a poleward movement of the permafrost extent (indicating a shrinking in permafrost area), and an increase in the active layer thickness in the permafrost region. These changes would reduce the surface albedo, and the earth system would absorb more solar radiation which would warm the earth's climate even more.

In recent years, a slight inland thickening and strong marginal thinning of the Greenland ice sheet produce a net loss of the ice mass. A model-projected warming in the twenty-first century would suggest a continued mass loss of the Greenland ice sheet. One model projection indicates that the entire Greenland ice sheet could completely melt away in the next 3,000 years if the current warm climate persists (Ridley et al., 2005). This would raise the global sea level by half a meter per century at peak melting. The changes in the Antarctic ice sheet as a whole are uncertain. But the Western Antarctic ice sheet is likely to lose more mass, or even totally collapse, if the future climate is warmer; a complete collapse of the West

Antarctic ice sheet would cause a global [sea level rise](#) of 5 m. It is hard to project how long this process will take from present ice sheet models.

In general, if the future climate is warmer than now projected by the IPCC models, it is certain the glaciers and ice caps will become smaller. Based on model simulations of 17 glaciers, the volume of loss of the glaciers is projected to be up to 60 % by 2050. Since the disappearance of these glaciers and ice caps is much faster than a potential reglaciation, the loss of the glaciers and ice caps may be irreversible, at least in some regions. Because the total mass of the global glaciers and ice caps is much smaller than the ice sheets of Greenland and Antarctic, the melting of these glaciers and ice caps would not raise the global sea level by much. However, it potentially can significantly impact the river runoff and the availability of freshwater supply, hence adversely affecting human activities.

Summary

The cryosphere is a very important part of the global climate system, and many important properties can be derived using remote sensing. The cryosphere played a significant role in the past changes of the earth's climate. Because of its high reflectivity (albedo) of solar radiation, shrinkage of the cryosphere coverage on the earth's surface would induce a higher absorption of the solar radiation by the earth's climate system which would enhance warming. A seasonal ice-free Arctic would enhance the hydrological cycle there, which will significantly affect human and marine life in the pan-Arctic region. A possible melt of the Greenland and West Antarctic ice sheets in the future would raise the global sea level markedly. Studies show that the climate was only a few degrees warmer during the last interglacial period than now and that the sea level was about 3–6 m higher. At that time, a very large portion of the Greenland ice sheet melted. If the sea level were to rise by 3 m in the next century or so, by the melting of the Greenland and West Antarctic ice sheets, human activities would be impacted in a momentous way.

CRYOSPHERE, CLIMATE CHANGE FEEDBACKS

Peter J. Minnett
 Rosenstiel School of Marine and Atmospheric Science,
 University of Miami, Miami, FL, USA

Definition

The term “feedback” is taken from electrical engineering and describes how a small part of the output of a circuit or a system, such as an amplifier, is fed back to become part of the input. A positive feedback loop results in a growth in the signal, or initial disturbance, and a negative feedback loop acts to diminish the effects of a disturbance, retaining the system close to a stable state. A positive feedback loop could push a hitherto stable system past a tipping point into another state. The concept of feedback loops is a very appealing idea for

geophysics and climate researchers, for example, as there are many levels of complexity that permit feedback loops of both signs that can stabilize the system to some disturbances or perturbations, and render it unstable to others (Bony et al., 2006).

Climate feedbacks

In the climate system, the simplest approach is to consider the change in the equilibrium temperature of the earth, or of a particular region (the temperature change being written as ΔT_d), that results directly from a change in the radiative forcing (ΔQ):

$$\Delta T_d = \lambda \Delta Q$$

where λ represents a sensitivity factor. For the direct radiative forcing of the climate system, λ is determined by the physical law relating radiation and temperature (Stefan-Boltzmann's Law) and has a value of about $0.25 \text{ K (Wm}^{-2})^{-1}$ for temperatures typical of the middle atmosphere. Thus, a change in radiative forcing of 4 Wm^{-2} would lead to a temperature change of about 1 K.

In the more realistic case, the climate changes involve feedbacks which modify ΔT_d to give the actual equilibrium temperature change (ΔT). Using the term "gain" (g) to represent the fraction of ΔT that is caused by feedback mechanisms, where g can be negative, but no larger than +1, then:

$$g = (\Delta T - \Delta T_d) / \Delta T$$

so that:

$$\Delta T = \Delta T_d / (1 - g)$$

Thus, a negative gain reduces the temperature change, and a value close to 1 leads to large amplification of the direct temperature change. There are generally several components in the climate gain factor which result from different physical mechanisms, and so the value of g is not a single value but varies according to the relative strengths of the different components, which in turn depend on the relative influence of the relevant parts of the climate system (NRC, 2003).

In the cryosphere, several feedbacks are also present in other parts of the climate system, but here they are rendered more extreme by the special characteristics of a region that are close to the freezing point of water. Several of the various components of the cryospheric feedbacks are accessible to satellite remote sensing, either directly through measurements of the critical variables, or through measurements of the consequences of the feedbacks.

In the polar regions, there are at least four major feedbacks that can, at least in principle, be monitored, or quantified, using remotely sensed data: the surface albedo-shortwave radiation feedback, the water-vapor feedback, the cloud radiative feedbacks, and the biogenic cloud condensation nuclei (CCN) feedback.

Surface albedo-shortwave radiative feedback

The rapid loss of summertime Arctic Ocean ice cover in recent years has focused attention on possible mechanisms for the accelerated loss, and the surface albedo feedback is one that is frequently mentioned. When the ocean is covered by ice, most of the incident solar radiation is reflected back through the atmosphere and to space. The ratio of the total amount of reflected energy to the incoming sunlight is called the albedo of the surface. Dry, fresh snow on sea ice can reflect as much as 90 % of the incident sunlight. The reflectivity varies with wavelength of the radiation (Hanesiak et al., 2001). As the temperature rises and the snow or ice begins to moisten, the albedo decreases, resulting in more of the solar energy being absorbed, and this leads to more melting of snow and ice. When melt ponds form, the surface albedo falls further and more solar energy is absorbed, leading to accelerated melting. The melting sea ice reveals the dark sea surface which has an albedo of <10 %. The heat resulting from the absorption of solar energy can be moved laterally by surface currents and brought into contact with sea ice, which it can melt from the sides or from beneath.

The situation on land is similar: when snow and ice melt away, they are replaced by bare ground or vegetation which generally has lower albedo and therefore absorbs more energy, hastening the melting of the remaining snow and ice nearby.

The albedo shortwave radiation feedback is a positive one, as the melting of the snow and ice reduces the surface albedo, resulting in the absorption of more sunlight, leading to yet more snow and ice melt (Curry et al., 1995).

The extent of polar sea ice is monitored very effectively from polar orbiting satellites using microwave radiometers and the surface reflectivity, and hence albedo is measured by satellite imaging radiometers operating in the visible part of the electromagnetic spectrum.

Water-vapor feedback

Water vapor in the atmosphere is a very potent greenhouse gas. This means the water molecules at a given height in the atmosphere absorb some of the infrared radiation emitted from the surface below and from the intervening atmosphere, radiation that would otherwise escape to space thereby cooling the planet; when that energy is reemitted, some of it propagates back toward the surface. The maximum amount of water vapor the atmosphere can hold without condensing is approximately exponentially dependent on the absolute temperature. Thus, as the temperature of the air rises, so does its ability to support an increasing water vapor burden and therefore its ability to intercept more of the outgoing infrared radiation. This is a positive feedback. The actual amount of water vapor in the atmosphere is also dependent on an available source of water, usually at the base of the atmosphere. A frozen surface is a poor source of moisture, so the atmosphere above is generally very dry, and the downward infrared radiation from the

atmospheric water vapor emission is small. Over open water, evaporation into the atmosphere leads to a moister atmosphere and increased downward infrared radiative heating of the surface. The advection of the moister atmosphere from over the open water to over sea-ice increases the radiative heating of the surface, leading to melting of the surface and increased evaporation – another positive feedback.

Although the atmospheric water vapor content, often called the precipitable water, can be measured quite accurately over the open oceans by microwave radiometers on spacecraft, the retrievals are not very accurate over land or over sea ice, or a surface comprised of mixed open water and ice. The atmospheric water vapor profile can be derived from measurements of infrared and microwave sounding radiometers, but again over land and over mixed ice and water surface, the retrievals are not very accurate. Thus the remote sensing of the water vapor and hence the direct quantification of this feedback is not possible using current remote sensing technology.

Cloud radiative feedbacks

A consequence of the increased atmospheric water vapor content resulting from evaporation over open water in polar regions is increased cloud cover. Often the low-level clouds that form over leads and polynyas (areas of open water surrounded by ice; Smith and Barber, 2007) can be traced many kilometers downwind, and are apparent in satellite imagery (Dethleff, 1994). Over the polar regions, as elsewhere, clouds can be carried great distances by the winds. The presence of clouds has two consequences on the surface radiative energy budget: they heat the surface by increasing the infrared radiation incident at the surface, and they cool the surface by casting shadows, that is, by scattering sunlight back to space. The former is a positive feedback, and the latter a negative one (Curry et al., 1996). Both are present at the same time, and the combined effect depends on the relative strengths of each (Hanafin and Minnett, 2001). The infrared heating depends on the amount, type, thickness, and height of the clouds and is present both night and day. The short-wave cooling occurs only in daylight and depends on the amount, type of clouds, and also on the solar zenith angle, and whether there are clouds across the face of the sun (Minnett, 1999). In general, the negative feedback that results in the cooling of the surface occurs in the polar summer, when the sun is higher in the sky, whereas the positive feedbacks occur when the incident solar radiation is small, when the sun is close to the horizon, or absent, as in the winter (Intrieri et al., 2002; Vavrus, 2004).

Clouds can be identified in satellite images, although this is more readily done when the clouds are illuminated by sunlight against a dark background of open water or dark vegetation. Over a bright frozen surface, the automatic identification of clouds is difficult and appreciable errors can occur. Similarly at night, when the

identification of clouds relies on a temperature contrast with respect to the surface, problems of misidentification can arise. Relatively new techniques using space-borne cloud radars and lidars show promise in improving the confident identification and classification of clouds and consequent improvements in the study of the cloud radiative feedbacks in the polar regions.

Biogenic cloud condensation nuclei (CCN) feedback

For clouds to form in the polar atmosphere, it is not sufficient that the water vapor content be at or above saturation, but also that there are small particles in the air that can act as cloud condensation nuclei. One group of CCNs over the oceans are minute salt crystals that result from the evaporation of spray droplets and another are derived from biological activity in the ocean. Airborne experiments over the Antarctic ice floes revealed bacteria and algal spores acting as CCNs (Saxena, 1983), and subsequently dimethylsulfide (DMS), a gas released from its precursor dimethyl sulfonium propionate (DMSP) at the ocean surface, have been found to be effective CCNs. DMSP is released when phytoplankton and algae die and decay. More recently, viruses, bacteria, and fragments of diatoms have been found to act as CCNs in the lower atmosphere over leads in the Arctic Ocean (Leck et al., 2004). The presence of biogenic material provides a possible feedback mechanism in the climate system: solar radiation is necessary for plankton to bloom, and when they die they release material that become CCNs, increasing the cloud amount, and this leads to a reduction in solar radiation reaching the surface – a negative feedback.

The presence of CCNs promotes not only cloud formation, but also influences the cloud properties. High concentrations of CCNs result in more and smaller droplets in the clouds, and this has two consequences. Firstly, the clouds have a higher albedo and therefore scatter more solar energy back to space, the Twomey Effect (initially described in terms of anthropogenic pollution in the atmosphere (Twomey, 1977)), and secondly, the smaller cloud droplets take longer to accrete to sizes that will lead to precipitation, so that the clouds live longer – the Albrecht Effect (Albrecht, 1989).

This biogenic negative feedback has been hypothesized to result in the appropriate amount of sunlight reaching the ocean surface to sustain the appropriate levels of biological activity. Too little sunlight reaching the surface, because of a local positive perturbation in the cloud cover, leads to less phytoplankton growth, fewer CCNs, and eventually more sunlight reaching the surface because fewer clouds are formed, or they have properties that are less effective in reducing the sunlight at the surface (Leck et al., 2004).

Unlike the other feedbacks, discussed briefly here, the biogenic feedback remains hypothetical and the links involved have not been quantitatively

substantiated. It remains a topic of research. The chlorophyll concentration in the upper ocean can be monitored using remotely sensed measurements of ocean color derived from reflected sunlight in the visible part of the spectrum, and clouds can be monitored from space, as mentioned above.

Summary

Climate feedbacks in polar regions act to accelerate or delay the effects of global change, not only at high latitudes, but worldwide. Because of the remoteness of the polar regions, and the difficulty of gathering appropriate measurements using conventional instrumentation, the study and monitoring of many of the components of the feedback loops are feasible only by using satellite remote sensing.

Definitions

(Land)fast ice. Sea ice attached to the shore or near-shore sea bed.

Nunatak. A mountain peak protruding through glacier ice.

Introduction

Remote sensing of the cryosphere has a 50 year history. We begin with an historical overview of aerial photography of the cryosphere – mainly glaciers and ice caps – and then proceed to satellite imagery and data for each of the major components of the cryosphere. In turn, we consider glaciers, snow cover, freshwater ice, sea ice, ice sheets and ice shelves, icebergs, and frozen ground.

Aerial photography

Glaciers and ice caps

Remote sensing of the cryosphere began with both vertical and oblique aerial photography of glaciers and ice caps. A massive campaign to photograph the Canadian Arctic was undertaken in the late 1940s–1950s (Dunbar and Greenway, 1956) and the photography covered all land areas. The US Geological Survey (USGS) photographed numerous glaciers in western North America and Alaska beginning in the 1950s (Post, 2005: <http://earthweb.ess.washington.edu/EPIC/Collections/Post/index.htm>).

The Austin Post aerial photograph collection begins in 1957 and continued through the 1980s. About 100,000 images on microfilm became a part of the World Data Center (WDC) for Glaciology collection when the WDC was transferred to the USGS in Tacoma in 1970 and to

the University of Colorado, Boulder, in 1976. This collection of the USGS Ice and Climate Project is known as the Post-Mayo-Krimmel Collection.

Aerial photography has continued to find applications. For example, snow patches remaining in late July in the Canadian Arctic have been mapped from air photographs for 1948–1983 by Lauriol et al. (1986). They found a high (0.93) correlation between the residual snow and maximum late winter snow thickness.

Satellite imagery and data

Aerial photography studies largely transitioned to satellite imaging from the Earth Resources Technology Satellite (ERTS) in July 1972 (renamed Landsat 1) and the subsequent Landsat series through Landsat 7 (15 m resolution) launched in 1999. The images are from a return beam vidicon (RBV) camera and multispectral scanner (MSS).

US military satellites in the CORONA and related programs collected over 800,000 diffraction-limited panoramic photographs with 2–7 m ground resolution from 1960 to 1972, which were declassified and made available for scientific use in the 1990s (McDonald, 1995). Mosaics of Greenland were developed from the Declassified Intelligence Satellite Photographs (DISP) by Zhou and Jezek (2002) in 1962 and 1963. Csatho et al. (2000) discuss the rectification of CORONA images for studying Greenland glacier motion and Altmaler and Kany (2002) use stereographic pairs for digital surface model generation.

In March 2002, the European Space Agency launched Envisat with the MEdium Resolution Imaging Spectrometer (MERIS) which has 15 channels in the 390–1,040 nm spectral range; a spatial resolution at nadir of 300 m is reduced on board to 1,200 m. In January 2006, the Japan Aerospace Exploration Agency (JAXA) launched the Advanced Land Observing Satellite (ALOS) with three remote sensing instruments: the Panchromatic Remote sensing Instrument for Stereo Mapping (PRISM) for digital elevation mapping with 2.5 m spatial resolution, the Advanced Visible and Near-Infrared Radiometer type 2 (AVNIR-2) for precise land coverage observation, and the Phased Array type L-band Synthetic Aperture Radar (PALSAR) for day-and-night and all-weather land observation. Imagery from commercial satellites has found occasional use but is too expensive for most research purposes. This includes data from the French Satellite Pour l'Observation de la Terre (SPOT) series, with SPOT 1 launched in 1986 and 5 in 2002 with 2.5–20 m resolution, the US Ikonos launched in 1999 with 1–4 m resolution and Quickbird launched in 2001 with 0.6–2.4 m resolution. The status of Russian environmental satellites in the METEOR, OKEAN, and RESURS series is reported by Asmus (2003).

Glaciers

Glacier mapping from Landsat Thematic Mapper (TM) data has followed several approaches (Paul, 2000). These involve: (1) manually delineating the glacier outline by

cursor tracking, (2) segmentation of ratio images, and (3) unsupervised or supervised classification. The first approach has been used to determine glacier length changes (Hall et al., 1992, for example). Various combinations of ratios have been used. Bayr et al. (1994) derive a glacier mask by using thresholds with ratio images of raw digital numbers from TM channels 4 and 5. Rott and Markl (1989) use atmospherically corrected spectral images of TM3/TM5 and TM4/TM5, with the help of thresholds to obtain a glacier mask. Paul noted that classification methods, both supervised and unsupervised, proved not to be suitable for glacier mapping.

Beginning in 1978, a major effort was undertaken by Williams and Ferrigno (1988) of the US Geological Survey to compile a Satellite Image Atlas of Glaciers of the World. The authors used maps; aerial photographs; Landsat 1, 2, and 3 MSS images; and Landsat 2 and 3 RBV images to inventory the areal distribution of glacier ice between about 82° north and south latitudes. Some later contributors also used Landsat 4 and 5 MSS and Thematic Mapper (TM), Landsat 7 Enhanced Thematic Mapper-Plus (ETM+), and other satellite images. There are 10 regional chapters: Those concerning Antarctica (B); Greenland (C); Continental Europe (E); Asia (F); Turkey, Iran, and Africa (G); Irian Jaya, Indonesia, and New Zealand (H); South America (I); North America excluding Alaska (J); and Alaska (K). All chapters are now accessible at <http://pubs.usgs.gov/pp/p1386/>.

A NASA-funded project for Global Land Ice Measurements from Space (GLIMS) is under way at the National Snow and Ice Data Center (NSIDC) (Armstrong et al., 2005b; <http://www.glims.org/>). It is an international project involving 60 institutions worldwide, with the goal of surveying a majority of the world's estimated 103,000 glaciers (Bishop et al., 2004). Currently over 96,000 glacier outlines are in the GLIMS database. A supplemental globally complete inventory was developed for the IPCC AR5 report and is available as the Randolph Glacier Inventory RGI3.0 (April 2013) from GLIMS. GLIMS uses data collected primarily by the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) instrument, aboard the Terra satellite, and the LANDSAT ETM+, along with historical observations. Analysis of changes in glacier extent using GLIMS data, earlier satellite imagery, and historical maps for the Eastern Pamir (Khromova et al., 2006) show that the glacier area decreased 7.8 % during 1978–1990, and 11.6 % in 1990–2001. In the Cordillera Blanca, Peru, Raup et al. (2007) show that glaciers receded by 11–30 % over the period 1962–2003; they also recognized inconsistencies in the earlier glacier mapping. Racoviteanu et al. (2008) use Spot 5 scenes from 2003 compared with aerial photography from 1970 for the Cordillera Blanca and report a 22.4 % loss in glacier area. High-resolution ALOS/PRISM data have been used for mapping glaciers in Eurasia and determining areal changes by comparison with earlier data by Aizen et al. (2007) and Surazakov et al. (2007).

There is still no single map of the world's glaciers. However, work is under way at the NSIDC to compile such a map using 500 m-resolution Moderate-Resolution Imaging Spectroradiometer (MODIS) images. The procedure involves determining whether a pixel has ever been snow free, by combining the lowest reflectance signatures for each pixel over several summer time periods in order to identify permanent snow and ice with the highest reflectance.

Glacier motion has been mapped with JERS-1 L-band SAR data. Strozzi et al. (2008) employ offset fields between pairs of JERS-1 satellite SAR data acquired in winter with 44 days time interval to estimate glacier motion on Svalbard, Novaya Zemlya, and Franz-Josef Land. The displacement maps show that the ice caps are divided into a number of clearly defined fast-flowing units with displacement larger than about 50 m/year with an estimated error on the order of 20 m/year.

Glacier mass balance has been estimated for three glaciers in the French Alps using a combination of SAR data and surface stakes (Dedieu et al., 2003). The essential key to using remote sensing is to obtain a high-resolution digital elevation model (DEM). This is possible from ASTER using stereoscopy, provided there are ground control points (GCPs) on and around the glaciers.

Snow cover

Hemispheric analysis of snow cover began in the United States in October 1966 from the polar orbiting Very High Resolution Radiometer (VHRR), with 3 km resolution, and continued with the use of AVHRR, GOES, and other mainly visible-band satellite data. The National Oceanic Atmospheric Administration (NOAA) issued weekly snow cover maps of the Northern Hemisphere that, beginning in 1972, were analyzed from the Advanced Very High Resolution Radiometer (AVHRR) instrument with 1.1 km resolution. The NOAA snow maps were generated from a polar stereographic grid whose pixel size ranged from 125×125 – 200×200 km depending on latitude. This now provides the longest time series of any satellite product. Since February 1997, it has been issued on a daily basis using the Interactive Multisensor Snow and Ice Mapping System (IMS) (Ramsay, 1998). Recent upgrades to the IMS are reported by Helfrich et al. (2007). They include: a 4 km-resolution grid output, ingest of an automated snow detection algorithm, expansion to global extent, and a static Digital Elevation Model for mapping based on elevation.

Global snow cover maps are now available from MODIS on Terra (February 2000–present) and Aqua (July 2002–present). There are daily, 8 day, and monthly global grids at 500 m and 0.05° resolution (<http://nsidc.org/data/modis/data.html>). Hall and Riggs (2007) provide an accuracy assessment for the Terra products. The overall absolute accuracy of the 500 m resolution swath and daily tile products is 93 %, but varies by land-cover type and

snow condition. The most frequent errors are due to snow/cloud discrimination problems; however, improvements in the MODIS cloud mask have occurred in each reprocessing. Detection of very thin snow (<1 cm thick) can also be problematic.

Global snow depth and water equivalent can be estimated from passive microwave data. One of the earliest algorithm applications was by Foster et al. (1980) using SMMR data for a hemispheric analysis. Chang et al. (1987, 1990) use the difference of the 18 and 37 GHz channels on SMMR to estimate snow volume in the Northern Hemisphere. The mean monthly snow volume ranges from about 1.5×10^{13} kg in summer to about 300×10^{13} kg in winter. Tait (1998) developed a series of algorithms for different land-cover types similar to those of Chang et al. (1987). Snow grain size, especially the presence of large depth hoar crystals, has a huge effect on microwave backscatter and so decreases the brightness temperature. Over the Canadian Prairies, operational analyses have been issued in near-real time since 1988/1989 using a vertically polarized gradient ratio algorithm $(37-19 \text{ V})/18$ (Goodison and Walker (1994). The algorithm was much improved by the use of a wet snow indicator. Foster et al. (1997) compare snow mass estimates from a prototype passive microwave snow algorithm, a revised algorithm, and a snow depth climatology.

Global maps of snow water equivalent from SMMR and SSM/I have been produced from 1978 to 2007 (with updates) by Armstrong et al. (2005a); (<http://nsidc.org/data/nsidc-0271.html>). The data are in 25 km grids but the radiometric information is from an area that is larger than 625 km^2 , so the gridded value represents a mean Snow Water Equivalent (SWE) for this area. There is decreased confidence in the SWE reliability and possible under-measurement in the following cases:

1. Mountainous areas with large topographic variability return low SWE values. Samples from these areas contain a mixed signal from a large footprint.
2. Forested areas return low mean SWE values, because the mixed signal includes emission from trees and the snow canopy as well as the underlying surface.
3. Areas near coastlines return low or no SWE values, because the mixed signal includes frozen and unfrozen water and land.
4. Areas containing melting snow or wet snow packs typical of maritime snow conditions return low or no SWE values, because the microwave emission from liquid water overwhelms scattering from the snow pack.
5. Shallow or intermittent snow during fall and early winter typically does not result in sufficient microwave scattering to reliably detect SWE.

Further details are available at http://nsidc.org/data/docs/daac/nsidc0271_ease_grid_swe_climatology.gd.html

The Advanced Microwave Scanning Radiometer for the Earth Observing System (AMSR-E) was launched on Aqua in May 2002. It measured horizontally and vertically polarized brightness temperatures at 6.9, 10.7, 18.7, 23.8,

36.5, and 89.0 GHz. The spatial resolution of the individual measurements varied from 5.4 km at 89 GHz to 56 km at 6.9 GHz. Thus, it had twice the resolution of SSM/I. A snow cover algorithm has been developed and tested by Chang et al. (2003). AMSR-E (SWE) and MODIS (snow extent) are available at NSIDC. AMSR-E was decommissioned on October 4, 2011.

Regional analyses of snow cover extent and characteristics have been carried out using Landsat Thematic Mapper data (Dozier and Marks, 1987; Martinec and Rango, 1987).

Subsequently, Airborne Visible/Infrared Imaging Spectrometer (AVIRIS) data have been used to map grain size and other snow characteristics via spectral mixture analysis. AVIRIS has 224 contiguous spectral channels with wavelengths from 400 to 2,500 nm. The spatial resolution is 4–20 m. The classification algorithm is based on the multiple end-member approach to spectral mixture analysis in which the spectral endmembers and the number of endmembers can vary on a pixel-by-pixel basis. This approach accounts for surface cover heterogeneity within a scene. The mixture analysis is operated on endmembers from a library of snow, vegetation, rock, soil, and lake ice spectra. Snow end members of varying grain size were produced with a radiative-transfer model (Painter et al., 1998, 2003; Dozier and Painter, 2004).

Algorithms are available to map snow extent (Shi and Dozier, 1993; Rott and Nagler, 1993; Shi and Dozier, 1997) and snow depth and density (Shi and Dozier, 1996) using SAR data. These approaches are valuable for small areas in mountain terrain but the limited swath coverage makes them impractical for continental regions.

The Cold Land Processes Experiment (CLPX), funded by NASA, was a multisensor, multi-scale approach to assess terrestrial snow cover, providing a comprehensive data set necessary to address several experiment objectives. Within a framework of nested study areas in the Rocky Mountains of Colorado, ranging from 1 ha to 160,000 km², intensive ground, airborne, and spaceborne observations were collected for mid-winter and spring intensive observation periods (IOPs) in 2002–2003. The three major questions of the mission (Cline et al., 1999) were as follows:

1. Can the components of the terrestrial cryosphere be observed from space accurately enough to identify meaningful climatic trends?
2. To what extent can snow and frozen ground information, deduced from remote sensing data, improve models of cold season processes, hydrologic forecasts, and forecasts of high-latitude ecosystem functions?
3. To what accuracy can SWE be estimated from remote sensing data, and is this sufficient for hydrological applications?

More specifically, the project aimed to:

- Evaluate and improve snow water equivalent retrieval algorithms for spaceborne passive microwave sensors such as SSM/I and AMSR-E

- Evaluate and improve radar retrieval algorithms for snow depth, density, and wetness, and soil freeze/thaw status
- Improve radar retrieval algorithms to enable discrimination of freeze/thaw status of snow, soil, and vegetation surfaces
- Examine the effects of spatial resolution on the skill of active and passive microwave remote sensing retrieval algorithms for snow and freeze/thaw status
- Examine the feasibility of coupling forward microwave radiative-transfer schemes to spatially distributed snow/soil models, to improve assimilation of microwave remote sensing data
- Examine the spatial variability of snow and frozen soil distributions in different environments and (a) improve the representation of subgrid-scale variability of snow and frozen soil in coupled and uncoupled land surface models, and (b) improve the representation of orographic precipitation (snowfall) in atmospheric models

Data collection focused on airborne measurements from five sensors each with a different spatial resolution. The NASA AIRSAR instrument collected synthetic aperture radar measurements at three frequencies (P-, L-, and C-bands) in both polarimetric and interferometric modes. The NASA POLSCAT instrument collected Ku-band scatterometer measurements. The NOAA PSR-A instrument collected passive microwave measurements at five frequencies ranging from 10.7 to 89 GHz. The similar Airborne Earth Science Microwave Imaging Radiometer (AESMIR) was flown during the 2003 campaigns to collect passive microwave measurements (at all AMSR-E frequencies from 6.9 to 89 GHz). The National Weather Service (NWS)/National Operational Hydrologic Remote Sensing Center (NOHRSC) airborne snow survey program also flew similar snow-detection sensors. An instrument measured terrestrial and atmospheric gamma radiation, which was used to determine snow water equivalent based on standard operational algorithms. At the two largest scales (33,000 and 142,000 km²), data collection focused on spaceborne measurements from several active and passive microwave and optical sensors.

Tedesco et al. (2005) show that airborne Polarimetric Scanning Radiometer data can be modeled by a log-normal distribution (Fraser, forested area) and by a bimodal distribution (North Park, patchy-snow, non-forested area). The brightness temperatures are resampled over a range of resolutions to study the effects of sensor resolution on the shape of the distribution, on the values of the average brightness temperatures, and on the standard deviations. The histograms become more uniform and the spatial information contained in the initial distribution is lost for a resolution >5,000 m in both areas. Tedesco et al. (2006) analyze the brightness temperatures of melting and refreezing snow using a truck-mounted radiometer at 6.7, 19, and 37 GHz and measuring brightness as a function of snow wetness. The physical model

reproduces brightness temperatures with a relative error of 3 % (8 K).

Haran (2003) provides MODIS radiances, reflectances, snow cover, and related grids for the CLPX IOPs in 2002–2003. Stankov and Gasiewski (2004) supply airborne multiband polarimetric brightness temperature images over three 25×25 km meso-scale study areas for both years. A listing of CLPX data sets is available at: <http://www.nsidc.org/data/clpx/#data>.

Freshwater ice

Ice forms seasonally on lakes, reservoirs, and rivers. A major problem for detection is the small spatial scale of rivers and small lakes. Detection of ice cover by passive microwave data is possible on large lakes and ice conditions have been routinely mapped on Great Slave and Great Bear Lakes in Northern Canada since April 1992 (Walker and Davey, 1993). DMSP SSM/I data are acquired with a focus on ice freeze-up and breakup. It has been found possible to discriminate between areas of ice cover and open water using SSM/I 85 GHz data. Airborne SAR data were used by Leconte and Klassen (1991) to determine lake and river ice features in Northern Manitoba, and Radarsat SAR is used routinely for ice classification and mapping over the Great Lakes (Leshkevich et al., 1998). Wynne et al. (1998) determined lake ice breakup dates from 1980 to 1994 for 81 lakes and reservoirs in the US Upper Midwest and portions of Canada (60°N , 105°W to 40°N , 85°W). Analyses of images from the visible band of the GOES-VISSR were used. The objectives were to investigate the utility of monitoring ice phenology as a climate indicator and to assess regional trends in lake ice breakup dates. MODIS 250 m-resolution data have been used for a study of ice-out dates in the Brooks Range (Kukthuroja et al., 2006). An initial problem was to construct a lake mask using 30 m TM imagery. Duguay and Lafleur (2003) combine optical and SAR data analysis to map ice thickness on shallow sub-Arctic lakes.

Sea ice

Sea ice in the Eurasian Arctic seas was routinely mapped by visual reconnaissance from aircraft flights in the Soviet Union starting in July 1933 and continuing until 1992 (Borodachev and Shilnikov, 2003). From the 1950s onward, 30–40 aircraft made 500–700 flights annually (Johannessen et al., 2007). The coverage was initially only in late summer, but by 1950, it was continuous throughout the year. Side-Looking Airborne Radar (SLAR) mapping was used from the mid-1960s and in 1983. SLR (Side-looking RADAR) was available from the Okean 01 series of satellites. Ice concentration and ice type were mapped at 10 to 30 day intervals. The chart records have been resumed since 1997 using satellite data. Early paper charts were digitized, and the entire series, including later charts that were produced entirely digitally, were converted to Sea Ice Grid (SIGRID) format at the Arctic and Antarctic Research Institute (AARI) in St. Petersburg, Russia.

NSIDC completed the conversion to EASE-Grid – a Lambert equal-area projection with 12.5 km cell size. Total ice concentration, as well as partial concentrations for multiyear, first-year, new/young ice, and fast ice, is available (Arctic and Antarctic Research Institute, 2007). Mahoney et al. (2008) analyzed sea ice extent in the Eurasian Arctic for 1933 to 2006 using the Soviet historical data.

The first aerial ice reconnaissance in Canada was completed during the winter of 1927–1928 by the Royal Canadian Air Force (RCAF) over Hudson Strait and Hudson Bay. In 1940, the Canadian Department of Transport Marine Services began an “Ice Patrol” in the Gulf of St. Lawrence. Summer patrols in the Arctic began in 1957. The first SLAR used for ice reconnaissance was installed in 1978; it had a 100 m resolution. SLAR measurements continue to be used along the eastern coast of Canada. Airborne Synthetic Aperture Radar (SAR) was introduced in 1990 with digital processing techniques and a resolution in the range of 5–30 m.

The use of satellite data from the visible and infrared Very High Resolution Radiometer (VHRR) began in 1966. In 1970, the National Oceanographic and Atmospheric Administration (NOAA) launched the first of a series of satellites with VHRR having an improved resolution of 1 km. In 1978, the first satellite carrying the improved Advanced Very High Resolution Radiometer (AVHRR) was launched. This series continues to this day.

Satellite reception at the Arctic and Antarctic Research Institute provides visible and infrared satellite images both from Russian (METEOR, OKEAN, RESURS) and US (NOAA) satellites. The OKEAN satellite also provides SLR and passive microwave data.

In December 1972, the National Aeronautics and Space Administration (NASA) launched the Electrically Scanning Microwave Radiometer (ESMR) on Nimbus 5. Until May 1977 this provided single channel horizontally polarized radiation at a frequency of 19 GHz. Its ability to operate in darkness and through cloud cover yielded the first comprehensive maps of polar sea ice extent for 1973–1976 (Zwally et al., 1983; Parkinson et al., 1987). The brightness temperature data gridded to 25 km (Parkinson et al., 1999) are available at: http://nsidc.org/data/docs/daac/nsidc0077_esmr_tbs.gd.html.

In October 1978, the Scanning Multichannel Microwave Radiometer (SMMR) was launched on Nimbus 7 and operated until August 1987. The instrument had three channels, two with dual polarization. Frequencies 18 and 37 GHz were used in various algorithms to derive sea ice concentrations for first-year and multiyear ice (Gloersen et al., 1992). The records continued with the Special Sensor Microwave Imager (SSM/I) on Defense Meteorological Program satellites. These instruments had five frequencies including 19 and 37 GHz.

Sea ice can be discriminated in the microwave regime through differences in the emissive characteristics between ice and ocean; in general, sea ice is more emissive than the open ocean. Use of combinations of frequencies

Cryosphere, Measurements and Applications,

Figure 1 Microwave brightness temperatures of sea ice and open water observed by Nimbus 7 SMMR in three regions of the Arctic, February 3–7, 1979. The regions A, B, and C are representative of first-year sea ice, multiyear ice, and open water, respectively. Hatched bands indicate $\pm$ one standard deviation about the mean (From Cavalieri et al., 1984; courtesy of the American Geophysical Union).

allows more accurate discrimination between ice and ocean as well as the ability to estimate fractional ice cover within regions of mixed ice and water. The NASA Team algorithm (Cavalieri et al., 1984) uses a polarization ratio and a gradient ratio.

The polarization ratio is:

$$PR_{[19V/H]} = \frac{T_B[19V] - T_B[19H]}{T_B[19V] + T_B[19H]}$$

The gradient ratio is:

$$GR_{[37V/19V]} = \frac{T_B[37V] - T_B[19V]}{T_B[37V] + T_B[19V]}$$

The PR is small for ice and large for water while the GR is small for first-year ice but large for multiyear ice. Figure 1 illustrates these points (Cavalieri et al., 1984). Combinations of PR and GR enable the T_B signatures to be interpreted as ice type and there are some eight or so algorithms in use for this purpose.

Another approach is used by the Bootstrap algorithm (Comiso, 1986), which employs linear combinations of 19 and 37 GHz frequencies at both horizontal and vertical polarizations to estimate fraction ice coverage. The NASA Team and Bootstrap, as well as other algorithms, require empirically derived “tie points,” or coefficients for pure surface types (100 % ice and 100 % water).

There are many uncertainties and limitations in using passive microwave data for sea ice detection. There are

errors due to ambiguous emissivity signals, particularly from surface melt water during summer and for thin ice. The available passive microwave frequencies can discriminate between at most three ice types, but often a region may have more than three unique microwave signatures. There can be erroneous ice retrievals over open water due to increased ocean surface emissivity from wind roughening. Atmospheric emission may be a factor in some conditions. Perhaps the major limitation is the low spatial resolution of passive microwave sensors, with footprints of 12–50 km. Thus, individual floes cannot be imaged and the ice edge location can be estimated to several kilometers accuracy at best. However, passive microwave data are a valuable source of sea ice information because it is sunlight independent and is generally not affected by clouds and other atmospheric sources. Also, passive microwave sensors have wide swaths and sun-synchronous orbits that provide frequent coverage of the polar regions. Thus, passive microwave data has provided a consistent and nearly complete daily record of sea ice conditions in both the Arctic and Antarctic since late 1978. Carsey (1992a) discusses the passive microwave properties of sea ice and the limitations of passive microwave remote sensing in more detail.

While the NASA Team and Bootstrap algorithm products are the most commonly used passive microwave sea ice estimates, several other algorithms have been developed, including the Cal/Val or AES York (Bjerkelund et al., 1990), Bristol (Hanna and Bamber, 2001), and Norsex (1983). All these algorithms make use of some combination of the 19 and 37 GHz channels. More recent algorithms have employed the higher frequency passive microwave channels on SSM/I and AMSR-E to obtain better spatial resolution and to resolve some of the surface ambiguities. These include the NASA Team 2 (Markus and Cavalieri, 2000) and the ARTIST (Spreen et al., 2008). The NASA Team 2 algorithm is used for the AMSR-E standard sea ice product (Comiso et al., 2003).

A comparison of the NASA Team and the Bootstrap algorithms is given by Comiso et al. (1997) and of the NASA Team, NASA Team 2, and the Bootstrap algorithms by Stroeve et al. (2001). Partington (2000) compared NASA Team and Cal/Val estimates and discussed the potential for a combined product using data fusion. Meier (2005) compares four different algorithms with AVHRR data. He finds that the smallest mean errors are from the Cal/Val and NASA Team-2 algorithms; the former tends to overestimate and the latter underestimate ice concentration relative to AVHRR in three near-marginal ice zones of the Arctic. Andersen et al. (2007) compared several algorithms and found significant differences in long-term trends depending on the algorithm, indicating potentially important influence of atmospheric and surface properties on the various sea ice algorithms.

Comiso and Nishio (2008) combine SSMR, SSM/I, and Advanced Microwave Scanning Radiometer (AMSR)-E data to show that the trend in ice area through 2006 in the Arctic is now slightly more negative at -4.0 ± 0.2 % per

decade, respectively, while the corresponding trend in the Antarctic remains slightly positive at $+1.7 \pm 0.3$ % per decade. The Arctic sea-ice cover, as revealed by microwave radiometry experienced a remarkable reduction in area in the summer of 2007, and again in 2012.

Carsey (1992a) provides a detailed and comprehensive treatment of sea ice remote sensing using both passive microwave and active radar remote sensing.

Passive microwave imagery is also useful for tracking large-scale sea ice motions using cross-correlated feature matching (e.g., Agnew et al., 1997; Kwok et al., 1998; Meier et al., 2000) or with a wavelet analysis approach (Liu and Cavalieri, 1998). SSM/I 85 GHz can estimate daily ice motions to within an RMS error of 6 km/day accuracy (Meier et al., 2000); averaging over longer time periods (Kwok et al., 1998) or using spatial interpolation (Meier et al., 2000) can reduce the error. Ice motion retrievals are limited during summer melt. Passive microwave sea ice motions have higher errors in the Antarctic (Kwok et al., 1998). The higher spatial resolution of AMSR-E can provide improved motion accuracy (Meier and Dai, 2006) and allow for better detection of summer motion through the use of the 18 GHz channel (Kwok, 2008). Because of the change in emissivity of sea ice during melt, passive microwave imagery is also useful for the determination of melt onset (Smith, 1998; Drobot and Anderson, 2001; Belchansky et al., 2004).

Radars that measure the power of the return pulse scattered back to the antenna can be used to derive geophysical parameters of the illuminated surface, or volume, based on the scattering principles of microwave electromagnetic radiation (Maurer, 2003). These instruments are known as “scatterometers.” The major instruments flown are the ESCAT, the European Space Agency’s (ESA) Earth Remote Sensing (ERS)-1 and -2 Active Microwave Instrument (C band, 3 GHz, V), the first of which operated between 1992 and 1996 and the second of which has been operating since 1996, and the NASA QuikSCAT SeaWinds instrument (Ku band, 13.6 GHz, V and H), flown from 1999 to present. Scatterometry is useful for measuring ice extent (Allen and Long, 2006; Anderson and Long, 2005; Remund and Long, 1999) and ice motion (Zhao et al., 2002; Haarpaintner, 2006). Resolution-enhanced scatterometer data using image reconstruction techniques have provided improved spatial resolution (Long et al., 1993), which potentially yields more precise ice edge position (Meier and Stroeve, 2008). Due to salinity differences between multiyear and first-year ice, scatterometer data can estimate seasonal and perennial ice coverage (e.g., Nghiem et al., 2007). Scatterometry is also useful for measuring the extent of snowmelt on sea ice due to its extreme sensitivity to the presence of liquid water.

Another active microwave sensor useful for sea ice studies is synthetic aperture radar. In contrast to scatterometers, it is an imaging radar that synthesizes images from multiple looks during the satellite’s motion in orbit to effectively create a large antenna and thus

obtain much higher spatial resolution. The Canadian RADARSAT-1 sensor has been providing SAR coverage of sea ice since 1995. RADARSAT-2 was launched in December 2007 and will take over SAR acquisition from RADARSAT-1. However, RADARSAT-2 is a purely commercial satellite and it is unlikely that data will be widely available to the science community. The resolution is high enough to capture small-scale ice motion and ice deformation events, allowing ice motion, ice age, ice volume, ice production, seasonal ice area to be estimated at fine spatial scales (Kwok and Cunningham, 2002; Kwok et al., 1995, 1998). The high-resolution, all-sky capabilities are particularly useful for operational analysis of sea ice, and SAR imagery is widely used by operational sea ice centers such as the Canadian Ice Service and the US National Ice Center (Bertoia et al., 2001). However, the narrow swath of SAR sensors limits repeat coverage to every 3–6 days in many regions of the Arctic. In addition, SAR imagery of sea ice can be difficult to interpret and efforts at automated analysis have been largely unsuccessful.

The determination of sea ice thickness remains a major challenge. Upward looking sonar (ULS) on submarines is the major source of ice thickness information in the Arctic (Rothrock et al., 1999). Ocean floor-mounted ULS have also provided ice thickness estimates but only in isolated locations (Vinje et al., 1998). Airborne electromagnetic induction instruments have been used experimentally and operationally since about 1990 (Haas and Eicken, 2001). Worby et al. (1999) describe its use over fast ice and pack ice in the Antarctic. More recently, autonomous underwater vehicles (AUVs) have been successfully employed to map the terrain of the underside of sea ice (Wadhams and Doble, 2008).

ERS radar altimetry has been used to estimate ice thickness in the Arctic (Laxon et al., 2003; Peacock and Laxon, 2004) and the Antarctic (Giles et al., 2008), but the coverage of the polar regions by the ERS orbit limits retrievals to the seasonal ice zones in the Arctic. Cryosat 2 with a radar altimeter was launched by ESA in April 2010 and is providing ice thickness and volume estimates for the Arctic (Laxon et al., 2012). The laser altimeter on the Ice, Cloud, and Land Elevation Satellite (ICESat) has been used to determine sea ice freeboard in the Arctic. Kwok et al. (2008) obtained average values of 43 cm over multiyear ice and 27 cm over first-year ice in February–March 2006. Uncertainties arise primarily through snow cover on the ice. Zwally et al. (2008) measured Antarctic ice thickness using ICESat.

There are considerable issues in determining sea ice thickness from altimeters and such measurements are still largely unvalidated. Because altimeters are measuring only freeboard, any errors in such estimates are magnified when deriving total ice thickness. The major uncertainty is snow thickness, which must be known to accurately account for its contribution to freeboard height (for laser altimeters that measure from the top of the snow surface) or for total freeboard density (for radar altimeters that

penetrate snow cover and measure from the snow/ice interface). However, while there is still considerable uncertainty in any absolute thickness estimates from altimeters, they appear to be able to capture seasonal and interannual variations well in sea ice thickness.

Lagrangian tracking of sea ice using passive microwave imagery and other sources provides a long history (since early 1980s) of ice age, a proxy for ice thickness (Maslanik et al., 2007); comparison with ICESat thickness indicates reasonable correlation between age and thickness on a basin scale up to ages of 9 years.

Ice sheets

Ice sheet remote sensing involves all wavelengths of the electromagnetic spectrum. Initial work was done with Landsat MSS images in the 1980s. Williams et al. (1982) assembled 4,270 Landsat scenes covering Antarctica to about 82 °S latitude. A Landsat MSS mosaic of the Ronne-Filchner ice shelf and Coats Land was georeferenced using measured ground control points by Sievers et al. (1989). A SAR mosaic from ERS-1 was georeferenced and is thought to be accurate to 50 m (Roth et al., 1993). The images are co-registered by either (1) matching fixed points such as nunataks projecting through the ice or (2) using the furnished coordinates based on orbital parameters. Note that georeferencing using the ephemeris data (furnished coordinates) has an advantage in the ice sheet interiors, where large areas are devoid of fixed rock outcrops. There are two methods to determine the glacial velocities: an interactive one in which crevasse patterns are visually traced (Lucchitta et al., 1993) and an autocorrelation program developed by Scambos et al. (1992).

Polar Pathfinder AVHRR products are available twice daily at 5 km resolution in Equal-Area Scalable Earth (EASE) Grid format (<http://nsidc.org/data/avhrr/>) for July 1981 through June 2005, and for shorter periods at 1.25 and 25 km resolution. The products include: clear-sky surface broadband albedo and skin temperature, solar zenith angle, surface type mask, cloud mask, orbit mask, and ice motion vectors (Maslanik et al., 1998; Scambos et al., 2000). Laine (2008) used these data to analyze albedo changes in the Antarctic. All sectors show slight increasing spring–summer albedo trends. The steepest ice sheet albedo trend of $0.0019 \pm 0.0009/\text{year}$ is found in the Ross Sea sector. The steepest sea ice albedo trend of $0.0044 \pm 0.0017/\text{year}$ occurs in the Pacific Ocean sector.

Multi-angle Imaging SpectroRadiometer (MISR) data have been used to determine the ice albedo over Greenland (Nolin et al., 2001). Stroeve and Nolin (2002) use two different methods to derive the snow albedo: one based on the spectral information and one utilizing the angular information from the MISR instrument. The latter method is based on a statistical relationship between in situ albedo measurements and the MISR red channel reflectance at all MISR viewing angles and is found to

give good agreement with the ground-based measurements. The spectral method is more sensitive to instrument calibration and shows bidirectional reflectance distribution function models and narrowband-to-broadband albedo relationships. The MISR sensor's ability to map glacier facies and roughness was explored and documented by Nolin et al. (2002).

The VELMAP project at NSIDC (<http://nsidc.org/data/velmap/>) aims to compile all ice flow data for the Antarctic continent. The project includes Landsat 7 and ASTER ice velocity maps while the second and third Radarsat Antarctic Mapping Missions provide data north of 80 °S. There are currently more than 130,000 ice vectors in the database.

Changes in the West Antarctic ice sheet since 1963 have been identified using formerly classified Corona images and recent data by Bindschadler and Vornberger (1998). They find that ice stream B has widened at a rate much faster than expected and its movement also slowed down. The available data are reviewed and described in Bindschadler and Seider (1998). A mosaic of the 1962–1963 Antarctic coast and ice shelves was compiled, and a grounding line for that time was calculated, from these data (Kim et al., 2006).

In 1997, the Canadian RADARSAT-1 satellite was rotated in orbit, so that its synthetic aperture radar (SAR) antenna looked south toward Antarctica. This permitted the first high-resolution mapping of the entire Antarctic continent to be accomplished in less than 3 weeks. Swath images representing calibrated radar backscatter data have been assembled into 90 tiles at 25 m resolution and an image mosaic available at 125 m to 1 km resolutions. The RADARSAT Image Map of Antarctica, 1999, is the product of the RADARSAT-1 Antarctic Mapping Project (RAMP). The mosaic provides a detailed look at ice sheet morphology, rock outcrops, research infrastructure, the coastline, and other features. Accompanying this mosaic is the high-resolution RAMP Digital Elevation Model (DEM) that combines topographic data from a variety of non-SAR sources to provide consistent coverage of all of Antarctica. Version 2 improves upon the original version by incorporating new topographic data, error corrections, extended coverage, and other modifications. The RAMP DEM is gridded at 200, 400, and 1,000 m.

There are large-scale spatial variations in radar brightness. The bright portion of Marie Byrd Land and the eastern Ross Ice Shelf probably represents the region where significant melting and refreezing occurred during an early 1990s melt event. Most of the coastal areas and much of the Antarctic Peninsula appear bright also because of summer melt. Remaining strong variations in radar brightness are poorly understood. Thousands of kilometer long curvilinear features across East Antarctica appear to follow ice divides separating the large catchment areas. On an intermediate scale, the East Antarctic Ice Sheet appears to be very “rough.” The texturing is probably due to the flow of the ice over the Wilkes subglacial basin located in George V Land. There the imagery shows subtle

rounded shapes similar in appearance to the signature of subglacial lakes such as Lake Vostok. In Queen Maud Land, East Antarctica, there are extensive ice stream and ice stream-like features. An enormous ice stream fed by a funnel-shaped catchment, reaching at least 800 km into East Antarctica, feeds Recovery Glacier, which enters the Filchner Ice Shelf. Megadunes and wind glaze regions were first identified as local features in Landsat TM, but are fully visible for the first time in the RAMP mosaic. Megadunes cover approximately one million square kilometers of the plateau surface (Fahnestock et al., 2006).

Using interferometry with SAR imagery obtained during the 1997 Antarctic Mapping Mission, ice velocity vectors were obtained over the East Antarctic ice streams. The upstream velocity of the Recovery Glacier is about 100 m/year but near the grounding line there is a local peak velocity of about 900 m/year.

Two digital image maps of surface morphology and optical snow grain size that cover the Antarctic continent and its surrounding islands have been prepared by NSIDC and the University of New Hampshire (Haran et al., 2005). The MODIS Mosaic of Antarctica (MOA) image maps are derived from composites of 260 MODIS orbit swaths. The MOA provides a cloud-free view of the ice sheet, ice shelves, and land surfaces, and a quantitative measure of optical snow grain size for snow- or ice-covered areas. Scambos et al. (2007) use MOA to provide continent-wide surface morphology and snow grain size.

Recently, the USGS with the British Antarctic Survey, NASA, and the National Science Foundation have produced a Landsat Image Mosaic of Antarctica (LIMA) from over 1,000 scenes of ETM+ to latitude 82.5°S at 15 m resolution (http://lima.usgs.gov/view_lima.php). Both the mosaic and the individual original Landsat images used in the compilation (which are nearly completely cloud-free scenes of the surface) are available online for free.

For Greenland, there has been albedo mapping with AVHRR (Stroeve et al., 1997) and MODIS (Liang et al., 2005). Ice velocity in ice streams has been derived from interferometric SAR (InSAR) (Joughin et al., 2000) and C-band SAR data from ERS-1 have been used to map the different snow and ice facies of the ice sheet (Fahnestock et al., 1993). Snow melt over the ice sheet has been mapped using SSM/I data by Abdalati and Steffen (1996) and using SMMR and SSM/I data by Mote and Anderson (1995). The latter used a threshold value of the 37 GHz brightness temperature while Abdalati and Steffen used a cross-polarized gradient ratio (XPGR), which is a normalized difference between the 19 GHz horizontally polarized and 37 GHz vertically polarized brightness temperatures. The threshold of $XPGR = -0.025$ is used to classify dry versus wet snow.

Changes in mass balance of the two major ice sheets have recently been derived from a variety of satellite measurements including the Gravity Recovery and Climate Experiment (GRACE) (Rignot and Thomas, 2002).

They show that the Greenland ice sheet is losing mass by near-coastal thinning. The West Antarctic ice sheet, with thickening in the west and thinning in the north, is probably thinning overall. The mass imbalance of the East Antarctic ice sheet is likely to be small, but even its sign is uncertain. The main objective of the laser altimetry data obtained from the Geoscience Laser Altimeter System (GLAS) on the Ice, Cloud, and land Elevation Satellite (ICESat) was to measure ice sheet elevations and changes in elevation (Schutz et al., 2005). GLAS provided global coverage between 86°N and 86°S. ICESat has seen wide use as a tool in investigating specific processes or regions, via profile comparisons over time. Among several results are the discovery of rapidly changing subglacial lake systems, which appear to fill and drain on short (month to year) timescales (Fricker et al., 2007; Shepherd and Wingham, 2007). Using satellite-derived surface elevation and velocity data, Howat et al. (2007) found large short-term variations in recent ice discharge and mass loss at two of Greenland's largest outlet glaciers (Howat et al., 2007).

Ice shelves

Iceberg calving from the Ross and Filchner ice shelves has been observed via satellite by the National Ice Center (NIC) originally using DMSP Optical Line Scanner (OLS) with 2.7 km resolution and AVHRR and subsequently MODIS and Envisat. Ballantyne and Long (2002) use scatterometer data to show the increasing numbers of icebergs detected since 1976. Antarctic icebergs are designated by the NIC as originating in one of four quadrants: A 0–90°W, B 90–180°W, C 180–90°E, and D 90–0°E. Iceberg B-15 broke off the Ross Ice Shelf in late March, 2000. Among the largest ever observed, this iceberg was approximately 270 km long $\times$ 40 km wide, nearly as large as the state of Connecticut.

MODIS satellite imagery revealed that the northern section of the 220 m-thick Larsen B ice shelf, on the eastern side of the Antarctic Peninsula, shattered and separated from the continent. A total of about 3,250 km² of shelf area disintegrated in a 35 day period beginning on January 31, 2002. The shattered ice formed a plume of thousands of icebergs adrift in the Weddell Sea. Over the last 5 years, the shelf has lost a total of 5,700 km², and is now about 40 % the size of its previous minimum stable extent. Glasser and Scambos (2008) found that ice-shelf breakup is not controlled simply by climate. A number of other atmospheric, oceanic, and glaciological factors are involved. The location and spacing of fractures on the ice shelf such as crevasses and rifts are very important because they determine the strength of the ice shelf.

On Ellesmere Island, Arctic Canada, the Ward Hunt Ice Shelf has undergone similar rapid changes since 2000. SAR imagery revealed an extensive serpentine crack, and secondary fractures, in 2002 (Mueller et al., 2003). In summer 2005, the Ayles Ice Shelf broke off forming an ice island (Copeland et al., 2007).

Icebergs

Icebergs were originally tracked by airborne reconnaissance in the Canadian Eastern Arctic and sub-Arctic. During 1960–1968, the International Ice Patrol used visual aerial reconnaissance. From 1963 to 1982, the Ice Patrol made iceberg survey flights north along the Labrador coast and into Baffin Bay. Side-looking airborne radar (SLAR) was introduced in 1983 and continues to be used. Following the advent of Radarsat-1 SAR (Power et al., 2001) in November 1995, the costly airborne surveys were discontinued by the Canadian Ice Service.

The Antarctic Meteorological Research Center at the University of Wisconsin-Madison provides near-real-time and archived imagery of Antarctic icebergs (<http://amrc.ssec.wisc.edu/index.html>). The images are from NOAA Polar Orbiting visible and IR band data. Brigham Young University, Provo, UT, produced enhanced resolution scatterometer backscatter images during July–September 1978 (from Seasat), July 1996–June 1997 (from NSCAT), 1992–2001 (from ERS-1 and 2), and June 1999 up to present (from QuikSCAT). Images were obtained from the Scatterometer Climate Record Pathfinder (SCP) project (Stuart et al., 2007). The initial position for each iceberg is located based on either (1) a position reported by the National Ice Center's web page (<http://www.natice.noaa.gov/>) or (2) by the sighting of a moving iceberg in a time series of scatterometer images. Ballantyne and Long (2002) used the archive to produce a long-term analysis of Antarctic iceberg activity.

Frozen ground

Frozen ground may be seasonal or perennial (permafrost). Permafrost is beneath the surface and not readily amenable to direct remote sensing (Zhang et al., 2004). However, the near-surface soil freeze/thaw status can be determined using satellite remote sensing data. SAR provides information on the timing, duration, and spatial progression of near-surface freeze/thaw in autumn and spring, for example. Freezing results in a large increase in the dielectric of soil and vegetation, which causes a large decrease in L-band (15–30 cm wavelength) and C-band (3.75–7.5 cm wavelength) radar backscatter (3 dB). Way et al. (1997) used the ERS-1 C-band instrument over central Canada, for example, to detect this. Passive microwave radiation (PMR) data offer similar information at lower spatial resolution. Frozen soils relative to unfrozen soils exhibit (1) lower thermal temperatures, (2) higher emissivity, and (3) lower brightness temperatures. The PMR algorithm for frozen soils is:

$$\frac{\partial}{\partial f} T_B(f) \leq P_{SG}$$

and

$$T_{B(37V)} \leq P_D$$

where the spectral gradient is in $K \text{ GHz}^{-1}$ and $T_{B(37V)}$ is in K. P_{SG} and P_D are the cutoff spectral gradient and brightness temperature, respectively. Based on these equations, surfaces can be classified as frozen, dry (and hot), wet (and cool), and mixed (Zuerndorfer and England, 1992). A frozen surface has low brightness temperature (37 GHz) and a relatively low negative spectral gradient. Zhang and Armstrong (2001) and Zhang et al. (2003) analyzed soil freeze/thaw status over the contiguous United States and southern Canada in winter 1997/1998. They used a negative spectral gradient and a threshold value of $P_{37} = 258.2 \text{ K}$. They found that almost 80 % of the time, the near-surface soil was frozen before snow accumulated on the ground. They applied the validated frozen soil algorithm to investigate near-surface soil freeze/thaw status from 1978 through 2003 over the Northern Hemisphere (Zhang and Armstrong, 2003). The long-term average maximum area extent of seasonally frozen ground, including the active layer over permafrost, is approximately 50.5 % of the landmass in the Northern Hemisphere. Preliminary results indicate that the extent of seasonally frozen ground has decreased about 15–20 % during the past few decades.

Smith et al. (2004) developed a freeze/thaw algorithm for SSM/I data and applied it for high northern latitudes for 1988–2002. They found a trend toward later autumn freeze-up in evergreen conifer forests in North America by 3.1 ± 1.2 days/decade while in Eurasia there was a trend toward earlier thaw dates in tundra (-3.3 ± 1.8 days/decade) and larch biomes (-4.5 ± 1.8 days/decade). Despite the trend toward earlier thaw dates in Eurasian larch forests, the growing season did not increase in length because of parallel changes in timing of the fall freeze (-5.4 ± 2.1 days/decade).

Conclusions

Remote sensing of the cryosphere has made major advances over the last three decades and has become an indispensable tool for cryospheric research, given the remote locations and hostile environments involved in the spatial distribution of many cryospheric variables. Beginning with aerial photography of glaciers, optical remote sensing then came into use in the 1960s–1970s for mapping snow cover and sea ice. The advent of passive microwave remote sensing in the 1970s eliminated most of the problems of cloud cover and illumination, and this advantage continued with the much higher resolution airborne and satellite radar data in the 1980s. Spatial resolution of optical sensors became much enhanced in the 1990s, and the 2000s have seen the use of satellite laser altimeter and gravity measurements. Techniques have also advanced with the direct production of DEMs from satellite data and ice motion studies using Interferometric SAR.

DATA ACCESS

Ron Weaver

National Snow and Ice Data Center, Cooperative
Institute for Research in Environmental Sciences,
University of Colorado, Boulder, CO, USA

Definition

Data access. A process through which users discover and acquire data. In the context of this encyclopedia, data refers to remote sensing data or ancillary or supportive data needed to utilize remote sensing data. Data access is part of the process of acquiring and managing digital data from remotely sensed sources. These processes are collectively considered part of ground data processing systems.

Historical perspective

Data access goes hand in hand with the launch of research and operational satellites in the 1960s. Access in the early 1970s consisted of provision of data to a limited user base most typically as hardcopy photographs or photographic film. Digital data were delivered on nine-track magnetic tapes, and analysis products were often line printer outputs (Swain and Phillips, 1973).

Data access systems of the late 1970s and early 1980s concentrated data access and analysis on workstations, where the scientist/user interacted with data access/analysis systems, which had direct attached disk (or tape) systems storage (Brown and Miller, 1984). The process consisted of the user logging onto these data systems, selecting and analyzing data as a timeshare user.

By the mid-1980s, the advent of the Compact Disk Read-Only Memory (CD-ROM) accelerated the evolution away from centralized data access and analysis computing systems. The CD-ROM allowed significant amounts of data to be cheaply distributed to users who analyzed these

data on their in-house workstations and in many cases personal computers (Kuykendall and Zion, 1984).

With the spread of the Internet, minicomputers, and subsequently the personal computer, digital data access options expanded. Increased bandwidth of the Internet allowed transfer of data electronically. The capabilities of workstations and personal computers allowed the individual research to perform more of their analysis on their local equipment.

Today data access is provided by a complex array of distributed data systems. Use of physical media in data distribution is greatly diminished. Within the data management systems of satellite data centers, data are increasingly housed on rotating disk, with users accessing these data by simple file transfer protocol (FTP) or a more complex array of data discovery, browse, and acquisition tools, many operating in a near-real-time environment. The role of tape media has become one of data security and backup rather than distribution.

Generalized functions of present-day data access systems

Data access per se is the end of a process that starts with data acquisition and ends with delivery of data to an end user or the end user's accessing computer system. Current data systems perform several functions, which typically reside between satellite ground systems and end user analysis systems. They consist of three components: ingest processes, data archival and management services, and finally data discovery and access/distribution services. Note that many systems also include data level change and geophysical data production services. Current day systems may also be distributed or virtual in design and implementation. This means that elements such as ingest or data management are geographically distributed but coupled by networks.

Ingest processing

Data are ingested from a ground system or a science data processing system. The ingest process guarantees that the data received is an exact copy of that transmitted from the antecedent provider and notifies the provider of successful ingest. Typically, data are inserted into online or tape archives with metadata placed in a database-driven inventory system.

Data management

The data management system must safely store the ingested data and provide metadata, allowing discovery and access and management over years to decades. Current systems store data in RAID archives, on magnetic tapes, or optical media. Since the mean lifetime of data storage systems is typically 3–5 years, long-term archival of data means that these data must be migrated from one media/storage environment to a newer system on a regular schedule.

Data discovery and access

Many interfaces between data and users exist, but the fundamental elements include processes to match the user query to the stored data attributes (e.g., data type, geographic location, time span, sensor or data set characteristic) and then delivery of appropriate data. Data visualization and data browse are often employed in data discovery interfaces. These techniques and services allow the user to assess data through visual display rather than just machine-readable digital formats. The discovery and access environment of modern [data access](#) systems is probably the most dynamically changing of any of the three components. As users develop new analysis techniques and tools, the data discovery and access system must adapt to efficiently feed data to these evolving user environments.

Trends in data access

The overall trend is to expose data through a rich variety of interfaces, tools, and services, which allow an increasingly diverse user community to gain access through interfaces native to their discipline or specific community. The access and delivery are becoming increasingly transparent to the end user, where the data resulting from a query simply appear on the user's desktop. Trends and important activity areas are described below, starting with technologies employed in data storage and management data and then access strategies and tools.

Data information technology systems

More remote sensing data are stored on rotating disk, either in RAID systems or in simple disk arrays. Staging data on Internet-accessible rotating disk allows exposure to all types of tools and services. Sometimes data are stored in distributed arrays of rotating disk. These data grids allow for geographic dispersal of data, which can help with network congestion and backup

security. Distributed data systems tend to increase the management demands of a data archive since tracking data physical location(s) is more complex. Eventually it is expected that digital data storage “clouds” will become commonplace. The implications of online storage of data for access are really two: first, the data are available with decreased latency and in some cases near real time, and second, more sophisticated and interactive visualization, browsing, and access tools and methods are possible, especially across multiple data types and data sets.

Remote sensing data access is moving rapidly toward electronic delivery of all data. While network bandwidth still limits the transfer of large volumes, the employment of geographic and temporal subsetting at the data center before delivery across the network can help to mitigate the bandwidth limitation.

Data access strategies

Increasingly, data are separated into levels generally organized according to the processing level. These data levels typically inform data access priorities, storage options, and delivery methods. For example, Level 0/1 data are delivered by bulk transfer methodologies such as the Unix File Transfer Protocol (FTP) or Secure FTP (SFTP) while Level 2–4 data more typically are accessed through viewers, tools, and services. The higher levels are placed in more responsive data systems so users can gain transparent and rapid access to these data sets.

Metadata, or descriptive information about data (see [Data Archival and Distribution](#)), is the lifeblood of data access. Users would not be able to access data in the Internet world without metadata-based search and discovery systems. The trend toward greater dependency on metadata-based searches is driven by both the increased number and diversity of available data sets and the expanded use of remote sensing data by less traditional earth and life science disciplines. To accommodate these needs, more rigor must be applied to the metadata including in some cases semantic translations of terminology between scientific disciplines.

Online data storage allows data delivery systems of a more complex nature. This capability, coupled with the needs of the earth science user community, is driving [data access](#) toward geographically enabled methods. Most importantly users are utilizing geographic information systems (GIS) from commercial vendors such as ESRI and open software consortiums such as the Open Geospatial Consortium. The use of GIS has pushed data providers to deliver data in geospatially enabled formats such as shapefiles and GeoTIFF.

A related trend is the explosion in the use of three-dimensional earth visualizers. Most notable in this category are the Google Earth, Microsoft Virtual Earth, and to a lesser degree open source solutions such as NASA's World Wind. These tools “drape” geolocated earth referenced data over a virtual globe.

Another trend in data access is the use of data delivery protocols that tie multiple data sets and distributed data centers together through one interface. Typically, these interfaces are designed for a specific user community but allow diverse data to be accessed using tools and metadata semantics familiar to the specific user community. Examples of these types of systems include the Open Data Access Protocol (OpenDAP) and the associated Thematic Realtime Environmental Distributed Data Services (THREDDS) system (OpenDAP, 2013; Unidata, 2013) and NASA's Earth Observing System Clearinghouse (ECHO, 2013). In these systems, the user queries data through a web-based Internet graphical user interface. Data are delivered to the user computer transparently, in some cases without clear knowledge of the source data location.

On the international scale, the *Global Earth Observation System of Systems (GEOSS)* is implementing distributed systems using Service-Oriented Architecture (SOA). SOA is based on the premise that complex systems may be broken into a collection of smaller related components. These smaller elements can be tied together through interfaces that intercommunicate application purpose and process logic. In a SOA environment, the service provider publishes a description of the service in a registry. Users can then access multiple services across the GEOSS and combine them in dynamic and varying ways to access data or produce end products.

This rich set of data sources and access tools provides the end user a broad array of options. While much of the data access and browse process is through human-machine interfaces, another growing trend is the use of machine-to-machine data access and automated workflow managers. These workflow systems allow the end user to assemble a processing system from data acquisition from the data archive to generation of a geophysical product and ultimately analysis of that product.

Locating data access systems

Many countries through various data access systems and protocols collect remote sensing data. These systems change often, and thus it is not practical to provide a listing of such systems here. However, two resources are useful for locating data, data access systems, and members of the international remote sensing community. The Global Change Master Directory (www.gcmd.nasa.gov) and its international partners maintain a catalog-level metadata collection for data sets relevant to the environmental research community. The Committee on Earth Observation Satellites (CEOS, www.ceos.org) is an international organization comprised of member countries that launch and operate civilian earth-observing satellites. The CEOS website maintains links to all participating member websites and their data systems. CEOS is also an active participant in the GEOSS effort. These are good first places to start a search for environmental remote sensing data.

Summary

Access systems are changing rapidly. Increasing availability of online (rotating disk) storage, improved network bandwidth, and software allowing distributed data systems and object-based data set retrieval add flexibility to data access and management systems. Users now access larger volumes of data more rapidly and transparently and with more powerful search and access choices than at any point in the short history of satellite remote sensing.

DATA ARCHIVAL AND DISTRIBUTION

Mark A. Parsons

Center for a Digital Society, Rensselaer Polytechnic Institute, Troy, NY, USA

Synonyms

Data curation; Data management; Data stewardship

Definition

Data Archiving. Formally preserving data and information and making it available for an identified but potentially large and changing group of data consumers or users (derived from the ISO standard Open Archival Information System (OAIS) Reference Model (CCSDS, 2002)). This definition applies to the archiving of any type of data or information whether it is a physical sample, a medieval manuscript, a photograph, or a digital data file. Remote-sensing data, with the exception of some early photography, are almost exclusively digital. Therefore, this entry focuses on digital data archiving.

Data Distribution. Movement of data from an archive to an individual user or system (see “[Data Access](#)”).

Digital Preservation. “The series of actions and interventions required to ensure continued and reliable access to authentic digital objects for as long as they are deemed to be of value. This encompasses not just technical activities, but also all of the strategic and organisational considerations that relate to the survival and management of digital material” (defined by the Digital Curation Centre (DCC) of the United Kingdom (Pennock, 2006, p. 1)).

Digital Curation. “Maintaining and adding value to a trusted body of digital information for current and future use; specifically, the active management and appraisal of data over the life cycle of scholarly and scientific materials” (defined by the DCC (<http://www.dcc.ac.uk/about/>)).

Data Management. “Data Resource Management is the development and execution of architectures, policies, practices and procedures that properly manage the full data life cycle needs of an enterprise” (defined by the Data Management Association International (<http://www.dama.org/i4a/pages/index.cfm?pageid=3339>)).

Data Stewardship. “All activities that preserve and improve the information content, accessibility, and usability of data and metadata. These activities include maintaining a scalable and reliable infrastructure to support long-term access and preservation, preserving [data access](#) and archive integrity during media migration and software evolution, providing effective data support services and tools for users, and enhancing data and metadata by adding information that is established throughout the data life cycle” (as defined by the National Research Council Committee on Archiving and Accessing Environmental and Geospatial Data at NOAA (NRC, 2007, p. 41)).

Introduction

Data archiving is an ancient discipline, dating back at least to the third century BC and the Library of Alexandria. Yet now the field is rapidly evolving in response to the new challenges created by the overwhelming growth of digital data. For ages, data archiving meant capturing information on paper in the form of documents, maps, and pictures; cataloging the information; and preserving the paper. Digital data changed all that. While well-preserved paper documents can last and be read for centuries, digital media are much less durable. Consider, e.g., the floppy disk: In a few short decades, it changed size and format several times and now is obsolete. You would be hard-pressed to find a computer that could read an 8 in. floppy disk from the 1970s, and even then, the disk would likely be damaged or the data on it corrupted. Not only do media change, but the data themselves can change in format, presentation, and content; and the volume of data continues to grow. This is especially true in remote sensing, where a growing number of increasingly high-resolution sensors generate terabytes (one terabyte = 1,012 bytes). A typical academic library might contain about two terabytes of printed information of new data every day (NRC, 2007). These data

Data Archival and Distribution, Figure 1 A simple representation of the data life cycle from NRC (2007).

may be in specialized, complex formats that can only be read or analyzed with specialized tools. The data are unique and unrepeatable because they describe features at a moment in time. Yet the data also change as they are calibrated, processed through new algorithms, combined with other data, or corrected for errors.

The dynamic nature of digital data, especially science data, led to the concept of the data life cycle. After data are first created or brought into an archive, users and data managers continually assess and sometimes improve the accuracy and understanding of the data and documentation (metadata). Archivists capture and maintain these improvements for future generations, and the process of acquisition, archiving, evaluation, and improvement continues for as long as the data are considered valuable (Figure 1).

To manage the data through their life cycle, it is insufficient to simply preserve, document, and distribute data. We must actively interact with users in order to curate or steward the data to maintain and increase the value of the data over time. This is reflected in the definitions above and in a growing body of national and international reports. This entry draws substantially from those reports including National Research Council recommendations to NOAA and NASA (NRC, 1998, 2003, 2004, 2007), the International Council for Science’s assessment report on scientific data (ICSU, 2004), the National Science Board’s report on long-lived data (NSB, 2005), and the US Global Climate Research Program’s report – *Global Change Science Requirements for Long-Term Archiving* (USGCRP, 1999).

Data Archiving Responsibilities

The OAIS Reference Model (CCSDS, 2002, pp. 3–1) describes six basic responsibilities of an archive. These responsibilities apply whether you are archiving a medieval manuscript or detailed remote-sensing

imagery, but remote-sensing data have unique considerations because of their volume, complexity, and dynamics. I review here the six OAIS responsibilities in light of data stewardship recommendations from the USGCRP, the NRC, and others to provide an overview of remote-sensing data archiving and distribution. Archiving is an ongoing process, not a onetime action, and the major challenges tend to be organizational and cultural rather than technical.

1. Negotiate for and accept appropriate information from information producers. Stewardship must begin early to ensure adequate planning and collection of information necessary for all archiving responsibilities. Ideally, the data archiving and stewardship process begins before the data are even collected. In remote sensing that might mean as soon as the initial instrument design. Therefore, “negotiation” could include describing how archivists or data scientists will be informed of the instrument design process, as well as determining data flow rates, volumes, formats, etc. Alternatively, archives may need to actively identify and locate data relevant to their community and negotiate for data transfer. Remote-sensing missions may spawn short-term algorithm and product development efforts that need to preserve their products. When archives accept higher-level products, they must also identify the dependencies in the data and ensure that all the related lower-level and ancillary products are also adequately archived and accessible somewhere. In some cases, it may be more appropriate to only archive lower-level products and produce higher-level products on demand. In which case it is especially crucial to track and record algorithm development. An archive may also need to seek out and preserve related ground-based data for validation, calibration, and processing of their remote-sensing data holdings (see “[Calibration and Validation](#)”). Occasionally, “data rescue” efforts may be necessary to acquire neglected, deteriorating, or disorganized data. In all situations, it is necessary to clearly plan roles and responsibilities throughout the full archiving process and to negotiate the cost and duration of archiving.
2. Obtain sufficient control of the information provided to the level needed to ensure long-term preservation. Typically, obtaining “sufficient control” of the data implies ingest or physical transfer of the data into the archive. Increasingly, however, archiving activities may be distributed across multiple organizations. For example, data may physically reside in one location, while archivists develop and maintain access services, user support, and data documentation elsewhere. Nevertheless, an archive must verify data locations and that data are not corrupted during transfer and that all the data in question are transferred. Formalized agreements may be necessary between ground systems, science teams, and archives that verify data flow. Verification techniques may include digital signatures,

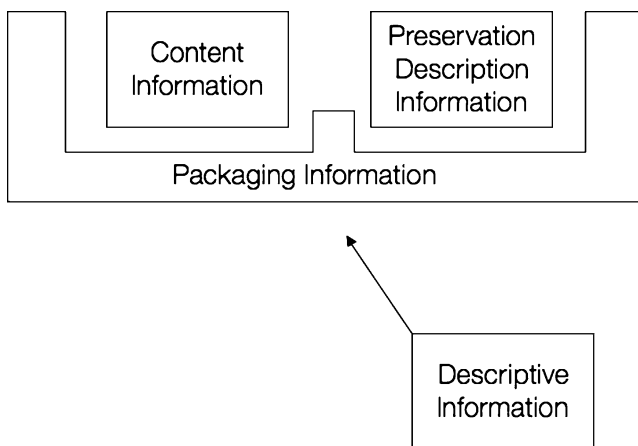

user authentication, and simply checking files against defined listings.

“Sufficient control” may also involve the ability to change the data. The archive may need to conduct quality control processes or reprocess the data with corrected algorithms. The archive will also need to continually revise and enhance the documentation and metadata (information about the data). Archives should work closely with data providers and others when making changes because ownership of digital data can be very complex. Creators of digital data, databases, algorithms, metadata, access tools, and contextual information can all have rights over the materials. Archives need to ensure fair attribution of data authors. (A developing best practice is to formally cite data authors and publishers much as you would a journal article or a book.) They may need to restrict or carefully document data use. They may not even have full control of the data because of privacy or security issues. Managing rights and data control is an ongoing and challenging aspect of data stewardship. See also “[Data Policies](#).”

3. Determine, either by itself or in conjunction with other parties, which communities should become the Designated Community (“Designated Community: An identified group of potential Consumers who should be able to understand a particular set of information. The Designated Community may be composed of multiple user communities” (CCSDS, 2002, pp. 1–10)) and, therefore, should be able to understand the information provided.

Defining the designated user community for a data set is a core responsibility of archiving that informs all other responsibilities. The data to be archived, how they are described, how they are presented, and how actively they are curated all depend on the needs of the designated community. Yet user communities change over time as products become better understood and new applications are conceived. Archivists should seek to maximize the use and value of their data by accommodating the broadest possible use including unanticipated use while discouraging scientifically inappropriate use. When developing data documentation, archivists must challenge their assumptions about the knowledge of data users and creators and write in language and detail appropriate to a broad community. They must clearly and explicitly describe data uncertainties and use durable, flexible, and understandable data formats. In short, they must actively engage with their community to understand how it is evolving (Parsons and Duerr, 2005). The designated community must also help determine what data should be archived and what data can be discarded (NRC, 2007).

4. Ensure that the information to be preserved is independently understandable to the Designated Community. In other words, the community should be able to understand the information without needing the assistance of the experts who produced the information. If data are

Data Archival and Distribution, Figure 2 Information package concepts and relationships according to the OAIS Reference Model (CCSDS, 2002).

to be “independently understandable” now and long into the future, we need to maintain and preserve the basic digital data set and a lot of other information describing the data set. The OAIS Reference Model uses the concept of “information packages,” to describe all the information (data and metadata) that needs to be preserved for a given data set. The model describes two core sets of information – “content information” and “preservation description information.” These are bound together in an archive with “packaging information” and made available to catalogs and data discovery tools through “descriptive information” (Figure 2).

Content information includes the actual data, i.e., the primary thing to be archived, and enough “representation information” for the designated community to understand what the data describe (represent) and basically how to use them. For example, representation information for a gridded, satellite-derived, snow cover data set would include detailed information on the data format, the dimensions and geolocation parameters for the grid, the values in the grid cells such as percent snow cover, and the date and time of the values. It would not include information on the sensor, the algorithms used to create the values, how the data relate to other data, etc. So while the content information is independently understandable at a crude level, for the data to be scientifically useful, you need the other core set of information in the package: the preservation description information.

Preservation description information is all the other information necessary to make the data truly useful and to ensure the data are adequately preserved. The information has four categories: Reference, Fixity, Provenance, and Context. Reference information includes things like object identifiers, aliases, file naming conventions, etc. Fixity information describes methods used to ensure there are no undocumented changes in the data

(e.g., digital signatures). These first two categories are mostly the concern of archivists. Provenance and context information, on the other hand, are of interest and are often created by both archivists and users.

Provenance information describes the history of the data set. This includes information on changes in media or transfer of data between institutions, but in remote sensing, it must often include information on types of calibration and validation (see entry *Calibration and Validation*), data processing levels, algorithms applied, etc. One must know precisely what version of data was used in an analysis to reproduce and verify the results. With the large volumes of remote-sensing data, higher-level products are often processed and delivered to users on demand. This creates challenges for both the archivist and user to track precisely which version of data was used for an application or analysis. Maintaining detailed information on sensor and algorithm development is especially critical when considering changes over time in long data records or time series.

Context information describes the background and circumstances that led to the creation of the data and the relationships between the data and other data sets and documents. With remote-sensing data, content information is probably the most complex and voluminous set of documentation in the information package. The USGCRP (1999), p. 32 provides a list of documentation to consider to ensure Earth science data remain scientifically useful. Most of this list can also serve as a description of context information for remote-sensing data. In particular:

- Instrument/sensor characteristics including preflight or preoperational performance measurements (e.g., spectral response, noise characteristics)
- Instrument/sensor calibration data and method
- Processing algorithms and their scientific basis, including complete description of any sampling or mapping algorithm used in creation of the product (e.g., contained in peer-reviewed papers, in some cases supplemented by thematic information introducing the data set or derived product)
- Complete information on any ancillary data or other data sets used in generation or calibration of the data set or derived product
- Processing history including versions of processing source code corresponding to versions of the data set or derived product held in the archive
- Quality assessment information
- Validation record, including identification of validation data sets
- Any changes in instrumentation, controlling agency, surrounding land use, and other factors that could influence the continuity of the record
- A bibliography of pertinent technical notes and articles, including refereed publications reporting on research using the data set
- Information received back from users of the data set or product

Full scientific understanding requires all this information. Yet different disciplines use terminology in different ways, potentially causing inconsistencies and misunderstandings. This is where specifying and adapting to changes in the designated community is most essential. Context information can be very dynamic and requires active curation by archivists in collaboration with users and providers. Furthermore, the complexity of the metadata does not relate directly to the volume of the data set. Smaller data sets, especially highly processed data, can require as much, or more, context information and active curation as large (lower-level) data sets.

The OAIS provides a good conceptual model for an information package, but it does not specify the precise content of the information. The data community has developed metadata standards that have more detail on the precise nature of information to be stored. Historically, the primary metadata content standard for remote-sensing data was the Federal Geographic Data Committee's *Content Standard for Digital Geospatial Metadata* with remote-sensing extensions (FGDC, 1998, 2002). Now, the ISO 19115 standard (ISO, 2006), largely based on the FGDC standards, is increasingly becoming the broader, more accepted standard. The FGDC/ISO standards are very detailed and complex, but they were not constructed according to the OAIS model. As such, they do not explicitly detail the components of an information package. They are particularly well suited to describe context and representation information and some Provenance, but formal practices have not been established to capture all the Preservation Description Information for remote-sensing data. The research library and archives community created the Preservation Metadata: Implementation Strategies (PREMIS) Working Group to develop a core set of implementable, preservation metadata guidelines based on the OAIS Reference Model (PREMIS Editorial Committee, 2008). Work is just beginning to apply PREMIS guidelines to the archiving of remote-sensing data in conjunction with traditional FGDC/ISO standards (see e.g., Duerr et al., (2009)). Keeping track of and implementing relevant standards is an ongoing archival activity.

5. Follow documented policies and procedures which ensure that the information is preserved against all reasonable contingencies and which enable the information to be disseminated as authenticated copies of the original, or as traceable to the original.

This describes the core preservation responsibility of an archive. Archives must, above all else, ensure the safety and integrity of the data in addition to developing and maintaining the necessary preservation description information described above. The large volumes of digital data present major archival challenges, hence the need for formally "documented policies and procedures." Procedures must, of course, be established for routine backups of the data, but the process goes beyond simple backups. It is important to maintain one or more physically separate duplicates of the data set from which a precise copy of the

original can be generated (e.g., files, databases, and schema). Disaster and security management plans should describe this process as well as security mechanisms for protecting the data from environmental hazards (e.g., floods, earthquakes), human attacks (computer viruses, unauthorized access), and technical hazards (changing software, media degradation) that could render the data unusable. A major activity is ensuring the integrity of the media holding the data. For large remote-sensing archives, media refreshment or migration is an ongoing operational activity. In other words, as soon as you finish migrating the entire collection from one medium (e.g., CDs) to another (e.g., tape archive), it may be necessary to start migrating to the next medium (e.g., RAID). Archivists must track media standards, durability, and use by the community. Furthermore, they must ensure that there is no undocumented change to the data during any sort of transfer. This requires the use of tools and procedures that ensure the "fixity" of the data as described in the prescription description information.

Changing data formats present similar challenges as changing media. Barnum and Kerchoff (2000) describe the risks of preserving information in proprietary format (e.g., MS Word). The companies that develop the formats may not stay in business or maintain backward compatibility with older versions. Remote-sensing data are usually in open formats, but much of the related context information may be in proprietary formats. Archives then need to migrate the data to a different format. This can lead to some loss of functionality or information with each migration. Even when the data are stored in a nonproprietary format (e.g., netCDF, HDF, shapefile), the data may not be able to be maintained forever in their original format. Even so-called standard formats evolve with changes in technology. "Self-describing" formats that include basic metadata in the data file are increasingly popular and useful in remote sensing, but these formats often require special tools to read and may not always be backward compatible with earlier versions (Duerr et al., 2004). Format evolution can cause particular problems in the Earth sciences where it is necessary to have a *consistent* long-term data series in order to detect subtle changes over time. These and related issues have led to calls for the establishment of a digital format registry (Abrams and Seaman, 2003; NSF/DELOS Working Group on Digital Archiving and Preservation, 2003). In response, the Harvard University Library has begun to develop the Global Digital Format Registry (<http://www.gdfr.info/index.html>). Another approach is to establish some sort of "universal data format." CCSDS (2008) is working in that direction by creating a standard approach for packaging data and metadata, including software, into a single package called an XML Formatted Data Unit (XFDU) to facilitate information transfer and archiving. Regardless of the approach used, it is important to recognize that while data may be archived in one (relatively stable) format, they may need to be distributed in multiple formats to best meet the needs of different users.

Maintaining processing algorithms is another challenge. It is not always cost effective or practical to preserve all levels of products. Instead an archive may only maintain the lower-level data and process higher-level products as required. This requires ensuring that the algorithms, where the code may be machine dependent, can always be run consistently. This could include maintaining the old computers to run the algorithm, recoding the algorithm to run on newer machines (producing the same results), or emulating an earlier computing environment on a new machine.

Overall, archivists need to carefully consider an appropriate balance of preservation strategies, including media and format *migration*, *normalization* on a few technology-independent standards, and emulation of earlier technologies (NSF and LoC, 2003). Much as with metadata standards, archivists must track developments and standards in media, formats, system architectures, and related technologies to keep their knowledge up to date in a quickly changing environment. This implies that training and formal professional development should also be included as archiving activities (ICSU, 2004).

6. Make the preserved information available to the Designated Community. Traditionally, making data available meant providing a basic catalog of items with controlled access to the materials, i.e., users had to request a copy or borrow the original. Now, with huge and growing volumes of remote-sensing data available through the Internet, [data access](#) has become a much more complex issue involving human interface design, information science, systems engineering, and other fields (see "[Data Access](#)"). Specialized data access mechanisms may be developed for different user communities, but an archive must, at a minimum, maintain a basic catalog of its holdings and distribute the data through standard mechanisms.

Most remote-sensing archives describe their data in directories using the FGDC or ISO metadata standards or some variant. Historically, they would distribute their data on media such as film, magnetic tape, or CD-ROM. Most data are now available through the Internet through standard methods such as FTP but increasingly through more sophisticated protocols such as defined by the Open Geospatial Consortium, the Open-source Project for a Network Data Access Protocol (OPeNDAP), and others. These more advanced protocols often help archives maintain their data in robust formats for preservation while serving the data in formats that work well with the changing tools of their user community. Although most data are distributed through the Internet, large volumes of data still need to be distributed on media. Current media include DVD and different forms of digital tape, but this will continue to change. Ultimately, the increasing volume of remote-sensing data makes distribution of the raw data impractical. Archives are increasingly providing tools that

enable users to subset and process data remotely so they do not need to actually transfer large volumes of data. Furthermore, remote-sensing data are highly distributed, so archives are increasingly working collaboratively to share data, computational power, and services across networks either through grid-computing networks, specialized data systems, or informally shared web services (see "[Data Access](#)," "[Data Archives and Repositories](#)," and "[International Collaboration](#)").

Conclusion

More scientific data have been collected and made available in the past 5 years than were available in all of history before that (Hey, 2006). Much of these data are derived from satellite and airborne remote-sensing instruments. It is vital to manage and preserve those data in accordance with recognized archival procedures, but with scientific data, especially complex remote-sensing data, an archival program must also include proper stewardship of the data. Archivists must actively engage the scientific community in the process to continually document and improve the data. They must develop and adhere to professional principles and best practices. Furthermore, these activities must continue as long as the data have value – potentially forever. This is a challenge for all of science and society. Technical issues present problems, but the largest challenge is creating the organizational and cultural changes necessary to sustain perpetual preservation and new knowledge.

Definitions

Active Archive, Active Archive Center. An organization whose role is to provide processing support, archiving, documentation, and distribution services for information and data during the life of a remote sensing mission, project, or program (derived from NASA's Strategic Evolution of Earth Science Enterprise Data Systems (SEEDS) Formulation Team Final Recommendations Report (SEEDS Formulation Team, 2003)).

Archive Center. Traditionally an archive, archive center, or records center has been defined as “an organization that collects the records of individuals, families, or other organizations; a collecting archives. . . The building (or portion thereof) housing archival collections” where records are “materials created or received by a person, family, or organization in the conduct of their affairs and preserved because of the enduring value. . .” as defined by the Society of American Archivists (Pearce-Moses, 2005). While accurate, this definition concentrates primarily on ingest and preservation activities, making no explicit mention of ensuring that the records preserved are accessible and usable. However, for digital materials such as most remote sensing data and information, accessibility and usability are key concerns and the definition that an archive is “an organization that intends to preserve information for access and use” (CCSDS, 2002) is beginning to be widely adopted.

Data Archive. “A repository which collects databases and data sets.” Defined by the Society of American Archivists (Pearce-Moses, 2005).

Data Center. “A data center (sometimes spelled datacenter) is a centralized repository, either physical or virtual, for the storage, management, and dissemination of data and information organized around a particular body of knowledge or pertaining to a particular business” (Godinho, 2008). Data centers are typically not tied to a single mission or project and may have a long-term charter (SEEDS Formulation Team 2003).

Data Library. An organization that houses a collection of published data. Derived from the library definition of the Society of American Archivists (Pearce-Moses, 2005).

Data Repository. “A place where things [in this case, data] can be stored and maintained; a storehouse. . . . A repository can be a place where multiple databases or files are located for distribution over a network, or

a repository can be a location that is directly accessible to the user. . . .” Defined by the Society of American Archivists (Pearce-Moses, 2005).

Long-Term Archive. “A data archive in which stewardship of data, products, information, and documentation is held on a permanent basis or until the data is considered to be of no value. The stewardship entails preservation, maintenance, and access of the data.” Defined by NASA’s Strategic Evolution of Earth Science Enterprise Data Systems (SEEDS) Formulation Team Final Recommendations Report (SEEDS Formulation Team 2003).

Introduction

Repositories and archives of Earth remote sensing data exist at all scales, from large, permanent organizations sanctioned by governments or intergovernmental organizations to small, ephemeral sites managed by an investigator as a part of their research. As such, it would be both futile and impossible to identify all of the archives scattered around the globe – there are simply too many small-scale, special purpose repositories to enumerate and the archives landscape changes too rapidly. The best that can be done is to categorize the general types of repositories that exist, describe their general characteristics, and discuss general trends. From largest to smallest scope, the range of archives can be divided into international systems of archives, national centers and systems, commercial archives, state and local agencies, and research archives.

International systems

The original system of World Data Centers (WDCs) was set up during the International Geophysical Year (IGY) in 1957–1958 under the sponsorship of the International Council of Scientific Unions (ICSU) to facilitate data archival and distribution, in particular distribution across cold war boundaries. Organized by scientific discipline, both Russian (WDCB’s), American (WDCA’s), and sometimes Western European (WDCC1’s), Asian, or Australian (WDCC2’s) archives were established with the assumption that holdings of each archive would be shared with its disciplinary partners. Funded by their host nation, WDCs provided their data freely to scientists in any country and were as a consequence forbidden from holding classified or confidential data (WDC Panel, 1996). The WDC system’s holdings were broader in scope than Earth remote sensing data, covering a wide range of solar, geophysical, and environmental disciplines. Roughly a dozen of the 52 centers held some Earth remote sensing data, while two WDCs explicitly dealt with remotely sensed land and atmosphere data (NGDC, 2003). In many cases, a WDC was colocated with a national data center specifically tasked and funded to handle the Earth remote sensing data acquired by that country. With the growth of technology and advent of high data rate remote sensing equipment, it proved impractical for these systems to deal with the quantities of data generated. In 2007 ICSU considered how best to “assert

a much-strategic leadership role on behalf of the global scientific community in relation to the policies, management, and stewardship of scientific data and information” (ICSU-SCID, 2007, p. 3). As a result, the former ICSU World Data Centres and former Federation of Astronomical and Geophysical data analysis Services (FAGS) were disbanded and a new World Data System (WDS) was created by the 29th ICSU General Assembly with the goals of

- Enabling universal and equitable access to quality-assured scientific data, data services, products and information,
- Ensuring long term data stewardship,
- Fostering compliance to agreed-upon data standards and conventions, and
- Providing mechanisms to facilitate and improve access to data and data products.

To ensure the authenticity, integrity, confidentiality and availability of the data and services within the WDS, organizations that wish to belong must undergo both initial and ongoing certification processes (ICSU-WDS, 2011). Many of the original WDCs and several of the FAGS, as well as several new organizations have gone through the initial process. At this juncture there are 52 regular members and 7 network partner members of the new WDS federation.

Also tracing their origin to the IGY, the World Meteorological Organization’s (WMO’s) Global Atmosphere Watch (GAW) has a system of five data centers that archive data from a worldwide network of stations. While the scope of data archived by these centers again is broader than Earth remote sensing data, atmospheric profile information provided by a variety of remote sensing instrumentation is archived. A total of five archives exist, organized by measurements including ozone, UV, solar radiation, greenhouse gases, and aerosols. Like many ICSU World Data Centers, the WMO data centers are operated and maintained by their individual host institutions and make data freely available to the scientific community. One difference between the two is an explicit requirement by the WMO DCs that any data used is acknowledged and that coauthorship be offered to the person who acquired and submitted the data to the archive (GAW, 2008).

In addition to the archive systems described above which are dedicated to providing the global science community with access to data, there are a wide variety of international programs and systems that acquire, archive, and distribute Earth remote sensing data as a by-product of their mission, a mission which is often focused on topics of societal concern such as emergency response and early warning of famines. In these cases, the products archived and distributed are often high-level-analysis products rather than raw data, and the long-term accessibility of the data may be uncertain. As an example, the UN-sponsored Global Information and Early Warning System (GIEWS) provides online access to 10 day NDVI-based vegetation anomaly maps for Africa, Asia,

Central and South America, and the Caribbean derived from SPOT imagery going back to 2004 (GIEWS, 2008).

National centers and systems

Over the years, ground-station-based national archives have proliferated. This trend began with the US series of Landsat spacecraft, which continuously transmit data so that any country capable of obtaining a ground system can acquire Landsat data within the mask of their ground station, and has increased dramatically in recent years as the cost of the infrastructure needed has dropped. Access to data from these archives depends not only on the access policy of the country in which the ground station is based but also on the terms of the agreement between that country and the country that owns the spacecraft. The situation may even be further complicated if commercial organizations are involved.

Similarly, due to the decreasing costs of information technology and the development of small, inexpensive spacecraft, the number of countries that own or are participating in a consortium that own a remote sensing satellite is steadily increasing. At this point more than 2 dozen countries, including several third world countries such as Nigeria, have remote sensing satellite systems on orbit or in development (Krebs, 2008). In many cases, development of the programs needed to support space and ground systems is seen as an “essential tool of Socio-Economic development and enhancement of the quality of life of its people” (NASRDA Undated, p. 4).

Irrespective of how the country obtains remote sensing data, its data archives are typically sponsored by one or more government agencies, typically those agencies responsible for space, meteorological information, disaster response, agriculture, or geological surveys. Archives are also often collocated with other entities such as a World Data Center, a ground station, a University, or other research organization.

Commercial archives

Remote sensing as a commercial enterprise can arguably be traced to the early 1920s with the commercial success of aerial photographic maps of Manhattan Island acquired by Sherman Fairchild (PAPA, 2001). Today there are literally hundreds of commercial aerial photographic and remote sensing companies of all sizes scattered around the globe utilizing the full range of airborne platforms including airplanes, helicopters, and balloons to acquire data for a wide range of purposes. Archive policies vary widely from company to company. Particularly for small companies, survival of the archive past the life of the original owner is often not ensured and depends strongly on the fate of the company itself. In some cases, the archive may be transferred to another commercial or government archive as a result. As an example, the estate of William H. Dehn donated the archive of sea ice charts of Alaska, the western Canadian Arctic, and Bering Sea acquired by his company Sea Ice Consultants, Inc. during the years

1953–1986 to the National Snow and Ice Data Center (<http://nsidc.org>) upon his death (NSIDC/WDC for Glaciology, 2005).

Commercial sales of space-based remote sensing data began in the 1980s with the US Landsat system, the French Satellite Probatoire d’Observation de la Terre (SPOT) program, and India’s Indian Remote Sensing Satellite (IRS-1A) series. In each of these cases, the spacecraft itself was government owned, though in the Landsat case the archive was privately marketed. While the Landsat commercialization model itself was not deemed a commercial success, the pattern of commercial sales of data from government-sponsored satellites or acquired by government-funded ground stations continues today throughout much of the world. In fact, a recent study indicates an increasing trend toward “public-private partnerships” for both the space and ground segments of high-resolution remote sensing systems (Gabrynowicz, 2007).

The first license granted to a private company to build and operate its own commercial remote sensing system was granted in 1993 to WorldView Imaging Corporation (now part of DigitalGlobe, <http://www.digitalglobe.com>). Since that year, several other commercial systems have been developed, most of which are targeted at the high-resolution, submeter imaging market where, unlike many science missions, imaging the entire globe especially on a repeating basis is not physically possible and archive growth is typically measured in square kilometers. Such companies, having made a significant investment in the data acquired, often consider themselves content providers, providing robust, redundant, geographically distributed archive systems for business continuity purposes. There are national security implications with the availability of these high-resolution data which one company in particular, ImageSat International, exploits explicitly with its access and pricing programs which offer “a completely autonomous, secret, regional very-high-resolution imaging capability” (<http://www.imagesatintl.com/>). National security concerns are one reason why access to data from these types of high-resolution systems is generally narrowing (Gabrynowicz, 2008). In recognition of the value to many customers of moderate resolution, large-area coverage, with frequent revisits for repetitive monitoring, yet another company, RapidEye has very recently launched a series of five identical spacecraft with 5 m resolution (<http://www.rapideye.com>).

State and local agencies

State and local agencies have been involved in the collection of Earth remote sensing data from the very earliest days, primarily as consumers of high-resolution imagery used for land use management and infrastructure planning. As such, many of the data products in their repositories may have restrictions against third party distribution depending on the terms under which the data were acquired. In many cases, products derived from the original imagery, often in a Geographic Information

System (GIS) format, are available. Such data may not be archived in a standard fashion, and long-term availability is uncertain.

Research data

Increasing amounts of data, including Earth remote sensing data, are being made available by a range of research projects, from individual investigators to larger coordinated observing programs. Typically, the data are available from a project website or via an ftp directory, and increasingly specific program funding is used to develop advanced access capabilities. There are a host of reasons for this trend. The decrease in cost of information technology makes it technically feasible for even small projects, while funding agencies are increasingly requiring that the data assets they paid for be shared (Lynch, 2008). On the other side of the funding equation, investigators are beginning to recognize that having data from their previous work available can help when it is time to get that next grant (Gogenini, 2008). Such data are rarely archived in a standard fashion, and the long-term availability beyond the term of the grant or program that funded the site is uncertain. Moreover, the infrastructure to acquire and formally archive these data for the long-term often does not exist, a situation that may be changing. For example, in the United States the National Science Foundation, through its DataNet program, is attempting to build the kind of sustainable data stewardship capabilities into university systems that would be needed to manage these data for the long term.

Conclusions

The archives and repositories landscape for Earth remote sensing data is undergoing a sea change, from a period where at the small scale there often was no long-term plan for data or data sharing and on the large scale data was held in large monolithic often less than easily accessible archives, toward a period where data at all scales may have a long-term home and be accessible albeit via an extremely diverse and distributed set of facilities. These trends are consistent with general trends in society as a whole, where increasing attention is paid to developing core competencies and other outsourcing activities. For archives this is leading to increasing distribution of functionality, where the organization with the IT infrastructure may not be the organization with the data stewardship knowledge and responsibility and neither may be the organization that provides advanced access services. For example, in the USA, after a contentious start, NOAA's Comprehensive Large Array Data Stewardship System (CLASS) has evolved to comprise solely NOAA's enterprise IT infrastructure in support of the archive missions of the NOAA Data Centers (Casey, 2008).

This trend toward diversification and distribution of functionality is in opposition to a trend toward the kinds of data and service interoperability needed to support both science which is becoming increasingly interdisciplinary

and to resolve societal needs as called for by the 2002 World Summit on Sustainable Development and by the Group of Eight. These high-level meetings called for international collaboration in making Earth observation data available to support nine areas of societal benefit. As a result, 74 governments, the European Commission, and "51 intergovernmental, international, and regional organizations with a mandate in Earth observation or related issues" are currently participating in the development of a Global Earth Observing System of Systems (GEOSS) (http://www.earthobservations.org/about_geo.shtml). Among the intergovernmental organizations participating in GEOSS, the Committee on Earth Observation Satellites (CEOS) is taking the lead in ensuring coordination of satellite-based remote sensing observations globally. If GEOSS is successfully implemented, access to the Earth remote sensing archived anywhere in the world will be available through a single portal.

Definition

Data assimilation is the process of characterizing a natural system by combining information from numerical models and observations. Such a characterization can have many purposes, including development of improved forecasts

and better process understanding, filling of data gaps, and design of environmental monitoring strategies. Depending on one's perspective, data assimilation either uses data to constrain a numerical model or uses a numerical model to extend and enhance data. Data assimilation applications are typically distinguished from classical parameter estimation applications by (1) an emphasis on spatially distributed dynamic systems (often described by partial differential equations) that yield large numbers of unknowns when discretized and (2) the need to merge large amounts of diverse data (e.g., obtained from instruments with differing accuracy, resolution, and coverage). The large size of most data assimilation problems makes computational efficiency an important design consideration.

History

Contemporary data assimilation descends from a number of different sources, most notably [weather forecasting](#) and classical least-squares estimation. Meteorological data assimilation developed more or less in parallel with numerical weather prediction and the increased availability of new data sources, including remote sensing measurements from airborne and satellite platforms. Meteorologists were among the first to appreciate the need to merge observations and models in a systematic way. This need motivated the development of a variety of objective analysis (or data assimilation) methods that relied on and extended traditional weather forecasting practices (Daley, 1991; Kalnay, 2003).

The traditional focus in meteorological data assimilation was on short- and medium-term forecasting. Now some operational weather forecasting centers also issue retrospective estimates (or “reanalyses”) of past conditions, which are increasingly being used to examine the effects of weather on ocean and land surface processes, chemical cycles, and ecosystems. Examples of reanalysis data include products issued by the US National Centers for Environmental Prediction (NCEP) (Kalnay et al., 1996; Kistler et al., 2001) and the European Centre for Medium-Range Weather Forecasts (ECMWF) (Uppala et al., 2005).

Oceanographers have also developed and applied data assimilation methods for forecasting (Hodur, 1997) and reanalysis (Wunsch and Heimbach, 2007). More recently, hydrologists, climatologists, atmospheric chemists, ecologists, geophysicists, and petroleum engineers have become interested in data assimilation, largely reflecting the availability of new modeling and observation capabilities in their fields (Kasibhatla et al., 2000; Lenters et al., 2000; McLaughlin, 2002; Trudinger et al., 2007; Oliver et al., 2008).

Methods

There are many ways to combine models and data – some quite general and others rather application specific. In most cases, data assimilation methods characterize

a system by generating from measurements point estimates of uncertain model variables. Point estimates are single values that are typically interpreted as “representative” or “most likely.” Many data assimilation problems in meteorology and geophysics are particularly concerned with point estimates of time-invariant parameters such as initial conditions and physical properties. In numerical weather prediction, the focus is usually on estimation of the initial values of the states (or prognostic variables) in the atmospheric equations of motion. The measurements used in meteorological data assimilation include ground-based weather data, radiosonde soundings, and electromagnetic measurements obtained from satellite sensors operating over a range of wavelengths and resolutions. By contrast, in solid earth geophysics and petroleum engineering, the focus is typically on estimation of uncertain rock properties, rather than initial conditions. Relevant measurements include borehole logs, oil and water production observations, and remotely sensed passive and active seismic data.

Point estimates of uncertain time-invariant model parameters are typically obtained by adjusting these parameters to obtain predictions that are as close as possible to measurements, subject to various constraints. This process may be viewed as a way to solve the inverse of the classical forward modeling problem (Banks and Kunisch, 1989). That is, the objective is to derive the model’s inputs from measurements of its outputs rather than to derive the model’s outputs from its inputs.

In many parameter estimation applications, the model structure is assumed to be perfect (or, equivalently, the model equations are imposed as strong constraints in the fitting process), but the measurements are assumed to be imperfect (i.e., the model is not expected to fit the data perfectly). Data assimilation methods that focus on point parameter estimates typically rely on statistical estimation techniques such as maximum likelihood and nonlinear least squares (Lewis et al., 2006). Depending on the context, the method may or may not make explicit probabilistic assumptions about uncertain parameters and/or measurement errors (McLaughlin et al., 2005). Most of the point parameter estimation techniques used in data assimilation involve optimization (e.g., maximization of an appropriate performance index). The optimization methods encountered in practice vary greatly depending on application but generally must be able to handle large nonlinear problems.

It is possible to generalize the parameter estimation process to account for imperfections in both the numerical model and the measurements. One option is to include dynamic (time-dependent) errors in the model state equations. These model errors (and possibly other uncertain model parameters) may be estimated from measurements. When a data assimilation algorithm provides for model errors, the estimated states are usually not the same as the predictions obtained from

an error-free model. Then the data assimilation process can truly be said to balance (or trade off) model and measurement information. The particular balance obtained depends on the relative confidence placed in the model and measurements. There are various probabilistic and deterministic methods for quantifying confidence. Data assimilation techniques that are able to account for model error include recursive (e.g., Kalman) filters and smoothers, expectation-maximization procedures, representer methods, and weak-constraint variational algorithms (Jazwinski, 1973; Moon, 1996; Bennett, 2002; Evensen, 2007).

In remote sensing applications, it is useful to distinguish between data assimilation methods, which typically rely on spatially distributed dynamic models derived from conservation principles, and retrieval methods, which typically rely on correlations between remotely sensed measurements and “ground truth” observations of the uncertain system states (Deepak et al., 1985). Retrieval methods are sometimes used to generate surrogate measurements for data assimilation algorithms. For example, surface soil moisture estimates obtained from a passive microwave radiobrightness retrieval algorithm can be treated as if they were observations in a land surface data assimilation procedure for estimating subsurface soil moisture profiles. An alternative to using retrieval outputs as surrogate measurements is to explicitly model the physical relationship between unobserved states (e.g., subsurface soil moisture) and the actual measurements (e.g., radiobrightness). The advantage of such a measurement model is that it may be applicable outside the range of conditions used to derive the retrieval algorithm. The relative merits of retrieval algorithms and data assimilation algorithms that explicitly model the measurement process are application dependent.

Interest is rapidly increasing in data assimilation methods that provide interval rather than point estimates for uncertain parameters and states. Interval estimates specify the range (and perhaps the probability) of possible values as well as a typical or most likely value. Such estimates usually require more effort to compute than point estimates, but they can be valuable in forecasting applications where it is important to assess predictability, evaluate the likelihood of extreme events, or bound the range of possible outcomes (Palmer and Hagedorn, 2006). A convenient way to obtain an interval estimate that incorporates measurement information is to use a Bayesian approach to update a prior ensemble (or population) of possible parameters and/or states. Methods for accomplishing this include various versions of the ensemble Kalman filter and smoother, particle filters, and Markov Chain Monte Carlo methods (Brooks, 1998; Arulampalam et al., 2002; Evensen, 2007). Most of these methods can account for both measurement and model errors. Ensemble-based interval estimation techniques are generally less used in practice than traditional point estimation techniques, but the pace of

methodological advances suggests that they will become more common in the near future.

Applications

Applications of data assimilation are widely documented in the meteorological and oceanographic literature and, to a lesser extent, in the literature of other fields. Meeting sessions and workshops devoted to data assimilation methods and applications are routinely sponsored by organizations such as the American Meteorological Society, the European Geological Society, the American Geophysical Union, the Society of Industrial and Applied Mathematics, and the Society of Petroleum Engineers. Most practical applications of data assimilation technology can be roughly divided into operational forecasting, primarily for predicting weather and ocean conditions, and reanalysis. The publication lists on the websites of the European Centre for Medium-Range Weather Forecasts (ECMWF, <http://www.ecmwf.int/>) and the National Center for Atmospheric Research (NCAR, <http://www.ncar.ucar.edu/>) provide convenient places to find typical examples of forecasting and reanalysis applications in meteorology. Some examples of oceanographic data assimilation applications are provided in the publication list found on the Estimating the Circulation and Climate of the Ocean (ECCO) program website (<http://www.ecco-group.org/>).

Data assimilation is becoming an adjunct to research in many fields, particularly when it is able to provide credible extensions to sparse data sets. A typical example is the use of global precipitation, wind, and air temperature reanalysis products issued by operational forecasting centers. These data products have been used to study topics as diverse as water supply, climate change, global chemical budgets, ecological cycles, and commodity pricing (Uppala et al., 2005). In fields such as pollution control and enhanced oil recovery, interest in data assimilation is motivated largely by the need for better information to guide real-time control decisions. Data assimilation appears to offer tangible benefits for such applications, but there have as yet been few large-scale demonstrations. It is likely that future data assimilation research will put more emphasis on decision-making and control. This will require the decision-making process to be explicitly included in the data assimilation problem formulation.

Conclusions

Data assimilation is a natural outgrowth of the classical scientific practice of trying to reconcile models and data. This is inevitably an iterative process which requires continual improvements in the models as well as continual efforts to collect new and more informative data. The analytical tools of data assimilation are intended to support and guide the broader effort to improve our understanding of natural systems.

Some of the factors that limit wider application of data assimilation methods include (1) fundamental uncertainties about the physical, chemical, and biological phenomena that are being modeled and observed; (2) the complexity and computational demands of the models and methods that need to be implemented in operational settings; (3) the dependence on simplifying assumptions that may be difficult to defend in practical situations; (4) the difficulty of insuring the quality of the large amounts of data that need to be assimilated; and (5) the need for better ways to distribute, document, and revise assimilation products. Current research is addressing most of these problems, but the rate of progress that can be expected in any particular application area is difficult to predict.

The factors that contribute most to the advancement of data assimilation practice are probably new instruments, better data sets, and fundamental improvements in modeling capabilities. But there is also room for advances in data assimilation methodology. Particularly promising directions for methodological research include (1) application of machine learning, image processing, and model reduction methods that address issues related to problem size and computational complexity; (2) robust nonlinear estimation techniques that are not restricted by traditional assumptions; (3) geometrical estimation methods that focus on the characterization and prediction of spatial patterns; (4) advanced pattern recognition and anomaly detection algorithms that can be used to automate the quality control process; and (5) web-based methods for documenting, displaying, and disseminating data assimilation products. Overall, there is good reason to expect data assimilation methods to become more powerful and more widely used as modeling, measurement, and computational technology continue to advance.

DATA POLICIES

Ray Harris
Department of Geography, University College London,
London, UK

Synonyms

Access principles; Data sharing

Definition

A set of principles governing the conditions under which data are provided to users.

Introduction

Data policies in remote sensing concern the conditions under which data are provided by the organizations that own and operate remote sensing satellites. The topics that are common in data policy cover ownership, intellectual property, standards, licensing, distribution, pricing, and archiving policies (Harris and Browning, 2005). Many of the organizations that own and operate remote sensing satellites are national governments, and so the data policies have dimensions that are political in nature because they are often part of government policy. Where private sector organizations are involved, they are given licenses to operate by national governments, and therefore, government policy still has a part to play. This discussion examines data policies from the perspective of the main organizations that have influenced data policy.

United Nations

In 1986, the United Nations (UN) agreed a set of 15 principles on remote sensing (Jasentuliyana, 1988; von der Dunk, 2002). The 15 principles were a compromise between those nations that saw outer space as a vertical extension of air space that they could control and those nations that wanted free and open access to outer space for the purposes of exploration. Of the 15 principles, it is especially useful to examine two of them. Principle IV strikes the contrast between “the freedom of the exploration and use of outer space on the basis of equality” on the one hand and “respect for the principle of full and permanent sovereignty of all States and peoples over their own wealth and natural resources” on the other. Remote sensing from satellites can provide more information to the satellite owner about the natural resources of a particular state or country (e.g., agriculture, forestry, minerals) than the information that the country has about its own resources. To answer the potential conflict in Principle IV, Principle XII maintains that the State that is sensed has the right of access to remote sensing data of its territory as soon as the data are produced, on a nondiscriminatory basis and on reasonable cost terms (von der Dunk, 2002). This means, for example, that Tunisia has

the right of access to satellite remote sensing data of its own territory, but it cannot prevent the data collection in the first place by satellites orbiting over its territory. By contrast, no other country can have access by right to the data of Tunisia, although other countries can purchase the data on the open market.

At the UNISPACE III conference in Vienna in 1999, a new International Charter on Space and Major Disasters was proposed (Ito, 2011). The idea of the Charter is to provide a single channel of remote sensing [data access](#) in times of natural or man-made disasters. The Charter is activated about 30–40 times per year and provides data free of charge in response to requests following disasters such as the tsunami in the Indian Ocean in 2004, Hurricane Katrina in the USA in 2005, Cyclone Nargis in Burma in 2008, and flooding in Gansu Province, China, in 2012. When a disaster occurs, one of the Charter members initiates a request for data. This request is then sent to the satellite operators so that they can task their satellites to acquire the data and make the data available as soon as possible to the authorized users. SPOT data are the most commonly used data type under the Charter.

World Meteorological Organization

The World Meteorological Organization (WMO) agreed in 1995 its Resolution 40 to provide advice on data access among its 187 member national meteorological services. The main text of Resolution 40 is:

Members [the national meteorological services] shall provide on a free and unrestricted basis essential data and products which are necessary for the provision of services in support of the protection of life and property and the well-being of all nations.

This core of free and unrestricted access does not apply to all data. In Europe, EUMETSAT interprets WMO Resolution 40 as applying to its 6-hourly Meteosat data, its WEFAX data, the Meteosat-derived products, and the data offered through its Meteosat Internet service (EUMETSAT, 2006). An interesting technique that EUMETSAT uses is to encrypt most of its Meteosat data, except for the 6 hourly transmissions that are provided free of charge.

United States

The approach by the United States (USA) on data policy for remote sensing is part of a wider policy on data produced by US federal government agencies. All federally produced data are made available to all users with no restrictions and with no copyright protection. This means that data produced by the federal agencies responsible for remote sensing (e.g., NASA and NOAA) are made available with no copyright restrictions on making and distributing further copies. The cost of the data is at the level termed COFUR – the cost of fulfilling a user request – which is usually the marginal cost of making

a CD of the data. NOAA provides data through online web access and by direct broadcast from its satellites free of charge.

The USA has a legal basis for its remote sensing data archive. Under Public Law 102–555 the National Satellite Land Remote Sensing Data Archive (NSLRSDA) was created to act as a long-term repository of Landsat and other remote sensing data. Those organizations in the USA that wish to dispose of a large archive of remote sensing data must first offer the archive to the NSLRSDA, which may accept the archive or may choose not to take it.

Europe

The European Space Agency (ESA) created a data policy for its Envisat satellite in 1998 (ESA, 1998). This data policy was subsequently made more generic and was applied to the other ESA remote sensing missions. The ESA data policy distinguished between two categories of the use of the data: Category 1 use for research and applications developments that are specifically in support of the Envisat mission objectives, including preparation for future operational use, and category 2 use for all other uses such as operational and commercial use (see entry [Operational Transition](#)). ESA is responsible for the distribution of category 1 use data at a marginal cost and delegates the distribution of category 2 use data to distributors that can both sell the Envisat data and develop their own products and services at market prices. In 2010 ESA revised its Earth observation data policy to distinguish between two groups of data sets: a free data set and a restrained data set. ESA retains some overlap with categories 1 and 2.

The European Union is involved in remote sensing data policy primarily as a user of data in support of its own policy objectives and as one of the leaders of the Global Monitoring for Environment and Security (GMES) initiative. In addition, there are certain directives of the European Union that are applicable to remote sensing [data access](#) to data about the environment created by public authorities (EurLex, 2006a), legal protection of databases (EurLex, 2006b), copyright protection, reuse of public sector information, and the INSPIRE directive concerning spatial data.

Security

During the twenty-first century, the USA has produced satellites capable of collecting remote sensing data at smaller and smaller pixel sizes, in 2012 down to 0.5 m pixel size (see entry [Commercial Remote Sensing](#)). This process has been characterized by formal government approval, for example, the 2003 National Security Presidential Directive which described the licensing of very-high-resolution commercial remote sensing satellites, stating how the US government would access these

data and how the data would fit in with US foreign policy (Anon, 2003).

India and Malaysia have shown considerable sensitivity over remote sensing data and national security. In India, data with a pixel size of less than 1 m are subject to a formal clearance procedure (ISRO, 2011). In Malaysia, data with a pixel size less than 5 m are subject to review by an internal security organization to check for sensitive areas. By contrast Google Earth and other data distribution mechanisms routinely provide very-high-resolution remote sensing data to all users without restriction.

Conclusion

Remote sensing is becoming more formal in its international structures (see entry *International Collaboration*). The Global Earth Observation System of Systems (GEOSS) is providing a mechanism for international coordination of existing remote sensing systems, of which the GMES initiative is the European component (Harris and Browning, 2005). GEOSS has developed a set of data sharing principles that requests full and open exchange of data. The European Space Agency and the European Union have produced a joint space policy that defines the nature of the relationships between the two organizations (Madders and Thiebault, 2007). More and more countries are producing national space laws or formal policies to guide their technical decisions, for example, Germany. As part of these formalization processes, data policies are becoming more explicit in defining how users can gain access to remote sensing data.

Definition

Synthetic Aperture Radar (SAR). A coherent radar system that records data in a way that allows later processing of the radar returns into images.

SAR Data Processing. The process by which radar signals are converted into images.

Introduction

The word **RADAR** is an acronym for Radio Detection and Ranging. A radar measures the distance, or *range*, to an object by transmitting an electromagnetic signal and receiving an echo reflected from the object. Since electromagnetic waves propagate at the speed of light, one only has to measure the time it takes the radar signal to propagate to the object and back to calculate the range to the object. The total distance traveled by the signal is twice the distance between the radar and the object, since the signal travels from the radar to the object and then back from the object to the radar after reflection. Therefore, once we measured the propagation time, we can easily calculate the distance to the target.

Radars provide their own signals to detect the presence of objects. Therefore, radars are known as *active* remote sensing instruments. Because the radar provides its own signal, it can operate during day or night. In addition, radar signals typically penetrate clouds and rain, which means that radar images can be acquired not only during day or night but also under (almost) all weather conditions. For this reason, radars are often referred to as *all-weather* instruments. Imaging remote sensing radars such as synthetic aperture radars (SAR) produce high-resolution (from submeter to few tens of meters) images of surfaces.

In this entry, we will describe the process by which radar signals are processed into high-resolution images.

Data Processing, SAR Sensors, Figure 1 Imaging geometry for a side-looking radar system.

Basic principles of radar imaging

Imaging radars generate surface images that are at first glance very similar to the more familiar images produced by instruments that operate in the visible or infrared parts of the electromagnetic spectrum. However, the principle behind the image generation is fundamentally different in the two cases. Visible and infrared sensors use a lens or mirror system to project the radiation from the scene on a “two-dimensional array of detectors” which could be an electronic array or, in earlier remote sensing instruments, a film using chemical processes. This imaging approach conserves the relative angular relationships between objects in the scene and their images in the focal plane. Because of this conservation of angular relationships, the resolution of the images depends on how far away the camera is from the scene it is imaging.

Imaging radars use a quite different mechanism to generate images, with the result that the image characteristics are also quite different from that of visible and infrared images. In order to separate objects in radar images in the cross-track direction and the along-track direction, two different methods are implemented. The *cross-track* direction, also known as the *range* direction in radar imaging, is the direction perpendicular to the direction in which the imaging platform is moving. In this direction, radar echoes are separated using the *time delay* between the echoes that are backscattered from the different surface elements. The *along-track* direction, also known as the *azimuth* direction, is the direction parallel to the movement of the imaging platform. The phase history of the

radar wave is used to separate surface pixels in the along-track dimension in the radar images.

Imaging radar sensors typically use an antenna which illuminates the surface to one side of the flight track. Usually the antenna has a fan beam which illuminates a highly elongated elliptical-shaped area on the surface as shown in Figure 1. The illuminated area across track defines the image *swath*. Within the illumination beam, the radar sensor transmits a very short effective pulse of electromagnetic energy. Echoes from surface points farther away along the cross-track coordinate will be received at proportionally later time (Figure 1). Thus, by dividing the receive time in increments of equal time bins, the surface can be subdivided into a series of *range bins*. As the platform moves, the sets of range bins are covered sequentially, thus allowing strip mapping of the surface line by line.

Radar resolution

The *resolution* of an image is defined as that separation between the two closest features that can still be resolved in the final image. First, consider two point targets that are separated in the line-of-sight (also known as *slant*) range direction by x_r . Because the radar waves propagate at the speed of light, the corresponding echoes will be separated by a time difference Δt equal to

$$\Delta t = 2x_r/c \quad (1)$$

where c is the speed of light and the factor 2 is included to account for the signal round trip propagation as described

Data Processing, SAR Sensors, Figure 2 The synthetic aperture radar integrates the signal from the scatterer for as long as the scatterer remains in the antenna beam.

before. Radar waves are usually not transmitted continuously; instead, radar usually transmits short bursts of energy known as radar *pulses*. The two features can be discriminated if the leading edge of the pulse returned from the second object is received later than the trailing edge of the pulse received from the first feature.

Therefore, the smallest separable time difference in the radar receiver is equal to the effective time length τ of the pulse. Thus, the slant range resolution of a radar is

$$2x_r/c = \tau \Rightarrow x_r = \frac{c\tau}{2} \quad (2)$$

Now let us consider the case of two objects separated by a distance x_g on the ground. The corresponding echoes will be separated by a time difference Δt equal to

$$\Delta t = 2x_r \sin \theta / c \quad (3)$$

The angle θ in Equation 3 is the *local* incidence angle. Therefore, the ground range resolution of the radar is given by

$$2x_r \sin \theta / c = \tau \Rightarrow x_r = \frac{c\tau}{2 \sin \theta} \quad (4)$$

Note that Equation 5 implies that the ground range resolution is different for different incidence angles.

These equations show that in order to produce high-resolution images, a radar system must utilize a short effective pulse length. In practice, this would require the transmission of very-high-power short-duration pulses, something that is quite difficult to do from space. To avoid this, most modern radar systems use *pulse modulation* schemes that allow us to transmit a physically long pulse, which can then be *compressed* during data processing to form a short effective pulse length. The most commonly

used modulation scheme is to vary the radar frequency linearly while the pulse is being transmitted. These signals are known as *chirp* signals, since the frequency change mimics the chirping of a bird. The effective pulse length of a chirp signal is

$$\tau = 1/B \quad (5)$$

where B represents the *bandwidth* of the modulation we used. Note that the resolution depends only on the bandwidth of the system, not how far away the object is.

Synthetic aperture radar

As the radar moves along the flight path, it transmits pulses of energy and records the reflected signals, as shown in Figure 1. When the radar data are processed, the position of the radar platform is taken into account when adding the signals to integrate the energy for the along-track direction. Consider the geometry shown in Figure 2. As the radar moves along the flight path, the distance between the radar and the scatterer changes, with the minimum distance occurring when the scatterer is directly broadside of the radar platform. The *phase* of the radar signal is given by $-4\pi R/\lambda$. The changing distance between the radar and the scatterer means that after range compression, the phase of the signal will be different for the different positions along the flight path.

The range between the radar and the scatterer as a function of position along the flight path is given by

$$R(s) = \sqrt{\rho_0^2 + v^2 s^2} \quad (6)$$

where ρ_0 is the range at closest approach to the scatterer, v is the velocity of the radar platform, and s is the time along the flight path (so-called *slow time*) with zero time at the

time of closest approach. To a good approximation for remote sensing radars, we can assume that $v s \ll \rho_0$. In this case, we can approximate the range as a function of slow time by a Taylor series expansion of the square root as

$$R(s) \approx \rho_0 + \frac{v^2}{2\rho_0} s^2 \quad (7)$$

The phase of the signal then becomes

$$\phi(s) = -\frac{4\pi R(s)}{\lambda} \approx -\frac{4\pi\rho_0}{\lambda} - \frac{2\pi v^2}{\rho_0 \lambda} s^2 \quad (8)$$

The instantaneous frequency of this signal is

$$f(s) = \frac{1}{2\pi} \frac{\partial \phi(s)}{\partial s} = -\frac{2v^2}{\rho_0 \lambda} s \quad (9)$$

This is the expression of a linear frequency chirp, that is, the instantaneous frequency of this signal varies linearly with slow time. To find the bandwidth of this signal, we have to find the maximum time that we can use in the signal integration. This maximum “integration time” is given by the amount of time that the scatterer will be in the antenna beam. For an antenna with a physical length L , the half-power horizontal beamwidth is $\theta_a = \lambda/L$, so that the scatterer at the range of closest approach ρ_0 is illuminated for a time

$$s_{tot} = \frac{\lambda \rho_0}{Lv} \quad (10)$$

Half of this time occurs when the radar is approaching the range of closest approach, and half of it is spent traveling away from the range of closest approach. Therefore, the bandwidth of the signal shown in Equation 9, which is the Doppler bandwidth of the SAR signal, is

$$B_D = \frac{2v}{L} \quad (11)$$

If this signal is filtered using a matched filter, the resulting compressed signal will have a width in time of $1/B_D$. Since the radar platform moves at a speed of v , this leads to an along-track resolution of

$$x_a = \frac{v}{B_D} = \frac{L}{2} \quad (12)$$

This result shows that the azimuth (or along-track) surface resolution for a synthetic aperture radar is equal to half the size of the physical antenna and is *independent of the distance between the sensor and the surface!* At first glance this result seems most unusual. It shows that a smaller antenna gives better resolution. This can be explained in the following way. The smaller the physical antenna is, the larger its footprint. This allows a longer observation time for each point on the surface, that is, a longer array can be synthesized. This longer synthetic array allows a larger Doppler bandwidth and hence a finer surface resolution. Similarly, if the range between the sensor and surface increases, the physical footprint increases leading to a longer observation time and larger Doppler bandwidth which counterbalances the increase in the range.

SAR processing implementation

Following the description above, we can now illustrate the most commonly used SAR processing algorithm known as the *rectangular imaging* algorithm (Curlander and McDonough, 1991). As the radar moves along its flight path, it transmits pulses of energy at a rate known as the *pulse repetition frequency* (PRF). For each pulse, the received echoes are digitized and stored as a column in a large matrix. Successive columns are recorded for successive pulses. Therefore, the column direction of the data array represents the slant range direction, while the row direction represents the along-track direction.

The SAR processing starts with a matched filter *compression* of the signals in each column of the matrix. This is known as *range compression*. For the mathematic

Data Processing, SAR Sensors, Figure 3 Graphic illustration of the rectangular SAR imaging algorithm. The image contains three point scatterers.

details of this process, see Elachi and van Zyl (2007). This matched filter operation is then repeated in the along-track direction using the appropriate signals with bandwidth given in Equation 10. This step in the processing is known as *azimuth compression*. In between these two steps, there is a step known as *range curvature correction*. This subtle point refers to the fact that as the range changes with slow time (see Equation 7), the echoes from the same point scatterer may not all be in the same row of the matrix. In fact, for spaceborne systems, the signal may extend over many rows as we move in the along-track direction. This is known as *range walk*. In order for us to perform the azimuth compression, we need to use only the signals that come from a particular scatterer. We can do this by predicting the range walk and then by resampling the signals so as to use the phase history along the curved range path.

The rectangular SAR processing process is illustrated graphically in Figure 3. In practice we utilize fast Fourier transforms to perform the matched filter operations.

Summary

SAR processing refers to the process of turning radar signals into images. Here we described the basics behind this imaging process. Many different SAR sensors are providing images on a routine basis today. Most of the research now involves the post-processing of SAR data to extract geophysical information from the images.

²Faculty of Electrical and Computer Engineering, University of Iceland, Reykjavik, Iceland

Definition

In the context of remote sensing-based land cover classification, many applications are aiming on the combination (i.e., fusion) of different data sources, for example, remote sensing images from different Earth Observation systems, in order to improve the classification accuracy. *Decision*

fusion is a potential approach and is defined as the concept of combining information from different data sources, after each source has been classified individually.

Introduction

Over the past decades, numerous Earth Observation (EO) systems have been launched, providing various data sets. On one hand, passive instruments, such as Landsat-5 TM and Landsat-7 ETM+, the ASTER sensor on the Terra platform, Envisat's MERIS, the SPOT satellites, and the AVNIR-2 on ALOS. These well-known optical EO systems are supplemented by passive instruments, such as ERS-2 SAR, Envisat ASAR, and Radarsat-1 as well as more recently launched systems such as TerraSAR-X, ALOS PALSAR, Cosmo-SkyMed, and the enhanced system Radarsat-2.

All these data and instruments have different characteristics, for example, different spatial and spectral resolutions, and diverse repetition rates. Moreover, multispectral and synthetic aperture radar (SAR) instruments operate in different wavelength range of the electromagnetic spectrum, ranging from visible to microwave. Thus, these EO systems provide different but complementary information. The combination of different data sources often improves the classification of remote sensing imagery in terms of the overall accuracy as demonstrated in several studies (e.g., Brisco and Brown, 1995; Benediktsson and Kanellopoulos, 1999; Michelson et al., 2000; Blaes et al., 2005; Waske and Benediktsson, 2007; Koetz et al., 2008).

Besides combining multisensor data sets, for example, multispectral and SAR imagery (Brisco and Brown, 1995; Waske and Benediktsson, 2007) or hyperspectral and LiDAR data (Koetz et al., 2008; Dalponte et al., 2008; Pedergrana et al., 2012), the combination of image time series is promising. Such multitemporal applications are usually more accurate, particularly when dealing with areas that are characterized by temporal variations, for example, due to crop phenology and plant status as in areas dominated by agricultural land use (Brisco and Brown, 1995; Chust et al., 2004; Blaes et al., 2005).

In addition to the use of multisensor images, the use of multisource data sets was discussed in several studies, including spatial information derived from the input images imagery (Benediktsson et al., 2003; Bruzzone and Carlin, 2006; Fauvel et al., 2008; Dalla Mura et al., 2010) and additional auxiliary data, for example, topographical information, statistical data on crop areas, and parcel boundaries or general environmental data (Briem et al., 2002; De Wit and Clevers, 2004; Wright and Gallant, 2007).

Overall, these studies clearly demonstrate that a combination of different data set (i.e., data fusion) is assumed to be valuable in terms of the classification accuracy. Regarding the increased availability of remote sensing imagery as well as auxiliary data, such multisource data

processing approaches become even more attractive. Consequently, the development of appropriate data fusion and classification of multisource data sets is an important ongoing research field of remote sensing (Richards, 2005).

In the following section, data fusion as a term is introduced. Afterward a very brief review of recent developments in land cover classification of remote sensing images is given, followed by a review of selected data fusion applications. Brief conclusions and future outlook are given in the final section.

Data fusion: definitions

Different authors have proposed a definition for data fusion. Hall and Llinas (1997) define data fusion as a process which deals with different data sources to achieve more accurate information in the context of decision making. Contrarily, Wald (1999) provides a more specific definition and defines data fusion as a formal concept of tools and means for joining different data sources. The aim of data fusion is generating information of “greater quality,” whereas the definition of “greater quality” depends on the particular application.

However, when dealing with remote sensing applications, data fusion mostly refers to the combination of image data. While the authors mentioned above present general definitions on data fusion, van Genderen and Pohl (1994) focused on image fusion, which was defined as “the combination of two or more different images to form a new image by using a certain algorithm.” In general, the fusion process can be distinguished into three main groups, depending on the level the fusion process is performed (Pohl and van Genderen, 1998):

- *Data-level fusion* refers to the concept of combining the original, raw sensor data on pixel level. The combined data provides the input for the classification algorithm.
- *Feature-level fusion* refers to the combination of different data sources, after a feature vector is extracted from each data set. The features are combined together into a single feature vector, which is used as input for the classifier algorithm.
- *Decision-level fusion* refers to a concept, which is based on the combination of different data sources, after each individual source has been handled separately. In contrast to the original information, the preliminary outputs are combined (e.g., different classification outputs) to generate a final result (see Figure 1).

However, considering the background of this entry, we note that data-level and feature-level fusion only constitute a modification of the available input data, not necessarily with direct consequences on the classification algorithms. Therefore, they are not discussed further here and only a brief review of selected applications is given, whereas decision-level fusion is discussed in more detail. Nevertheless, the discussion of the classifier algorithm itself would be beyond the scope of this entry. A general overview of classification of remote sensing data is given in the entry *Pattern*

Decision Fusion, Classification of Multisource Data,

Recognition and Classification in this book. The interested reader is also referred to one of several textbooks (e.g., Duda et al., 2000; Richards and Jia, 2005) for a detailed introduction of pattern recognition and classification.

Enhanced land cover classification by decision fusion

General developments in remote sensing land cover classification

Recent developments in the classification of remote sensing data have been driven by different factors, such as improved computer power, enhanced Earth Observation systems, and increased requirements on operational applications. While common applications are often based on statistical approaches, which were usually directly taken from the field of signal processing, the increased availability of multisource data sets demands more sophisticated methods (Richards, 2005; Jain et al., 2000). These facts result among others in a change from statistical approaches to more powerful machine learning algorithms.

Nevertheless, well-known statistical classifiers have been used in several multisource remote sensing applications. The conceptually simplest application is based on the stacked vector approach, which uses a composite vector with components from all of the data sources, for example, the digital numbers of each pixel. Although the well-known Gaussian maximum likelihood classifier

was used successfully in this context (e.g., Brisco and Brown, 1995; Chust et al., 2004; Huang et al., 2007), such method is often not adequate when classifying multisource and multitemporal data sets. Different sources can often not be described by a common statistical model, such as a multivariate Gaussian model. Moreover, individual data sources may not be equally reliable. One data set, for example, an image from a specific acquisition date, might be more relevant to classify a specific class, while another image is more applicable to discriminate between other land cover classes. Thus, a weighting of the different data sets could be useful in this context, which statistical techniques usually not allow.

Because of the above, distribution-free or nonparametric techniques are usually more adequate for multisource applications. Neural networks (Benediktsson et al., 1990; Serpico and Roli, 1995), self-learning decision trees (Fitzgerald and Lees, 1994; Friedl and Brodley, 1997), and Support vector machines (SVMs) (Huang et al., 2002; Foody and Mathur, 2004) are some examples of well-known such methods, which have been successfully used in the field of remote sensing. These methods still exhibit further development and adaption, for example, the use of support vector machines in the context of semi-supervised and ill-posed classification problems (Bruzzone et al., 2006; Chi and Bruzzone, 2007) or introducing a kernel framework for multitemporal and multisensor studies (Camps-Valls et al., 2008). Import vector machines (IVMs) are a promising alternative that have been very recently introduced on context of remote sensing. Experimental results show that SVM and IVM perform almost similarly in terms of accuracies, while the probabilities provided by IVM are more reliable, when compared to the probabilistic outputs provided by SVM. This fact is particularly interesting, because probabilities can be used for additional image analysis (Roscher et al., 2012).

Because the above methods usually do not require any prior assumptions about the distribution of input data, as is the case for the maximum likelihood classifier, they are usually better suited for the classification of multisource data sets.

Another development in machine learning and pattern recognition is the concept of multiple classifier systems or classifier ensembles that seems particularly interesting for multisource and high-dimensional remote sensing data sets (Briem et al., 2002; Waske and van der Linden, 2008; Cheung-Wai Chan and Paelinckx, 2008; Waske et al., 2010). In contrast to a regular classification, which is based on one classifier, a set of classifiers is used to generate the final classification results. The approach assumes that different independent classifiers generate individual errors, which are not generated by the majority of the other classifiers (Polikar, 2006).

While many classifier systems combine different variations of the same algorithm, for example, bagging, boosting, and random subspace methods, other applications combine different algorithms (Benediktsson and Kanellopoulos, 1999; Steele, 2000; Waske and van der Linden, 2008). One reason for the latter approach might

be that one method is better to describe one part of the feature space, whereas another algorithm performs better in another part of the feature space (Jain et al., 2000). Thus, these approaches seem particularly interesting for classifying multisource data sets.

Enhanced land cover classification by decision fusion

Several multisource applications are based on decision fusion, an approach which has been used successfully for different purposes and data types (e.g., Jeon and Landgrebe, 1999; Benediktsson and Kanellopoulos, 1999; Bachmann et al., 2003; Fauvel et al., 2006; Gamba et al., 2007; Waske and Benediktsson, 2007). Following the concept of decision fusion, the information from different data sources is combined, after each source has been classified separately.

In Benediktsson and Kanellopoulos (1999), decision fusion was used for the classification of multisensor data (i.e., multispectral and SAR data) as well as a hyperspectral imagery, data set, which was separated into different subsets. Contrary to the multisensor application, which already contains different data sets, the hyperspectral data are divided into several subsets, before the decision fusion is performed. Using the correlation between individual bands, the hyperspectral image is divided into several subsets. Afterward each subset is individually classified by a statistical classifier and a neural network. To generate the final result, the outputs were combined by decision fusion.

Jeon and Landgrebe (1999) introduced the concept for the classification of multitemporal imagery and discussed the use of different fusion strategies. The enhanced classification of very-high-resolution imagery was discussed in Gamba et al. (2007). After separating boundary and non-boundary pixels into two subsets, each subset was classified individually and the final map was generated by decision fusion of the preliminary outputs. Waske and Benediktsson (2007) discussed the use of different algorithms and approaches, including decision fusion, for the classification of multisource data set from an agricultural area. The results clearly demonstrate that the decision fusion outperforms other classification techniques in terms of accuracy.

Although these studies are based in general on the concept of decision fusion, the strategies, which were used for the fusion process, differ. Several methods have been introduced (Kuncheva, 2004), depending among others on the derived output of the classifiers (i.e., class labels and class probabilities, respectively). These methods comprise, for example, among others, a simple majority vote for class labels, average and weighted average rules for class probabilities, as well as more sophisticated approaches as fuzzy integral, Dempster-Shafer theory, and consensus theory (see Kuncheva, 2004 for a review).

The fusion may be based on consensus theory, for example, that employs single probability functions to summarize estimates from various classifiers by

consensus rules (Benediktsson and Swain, 1992). The linear opinion pool and the logarithmic opinion pool are common consensus rules, which are based on the weighted sum and the weighted products of the source-specific a posteriori probabilities. Thus, these approaches require the costly selection of weights, which generally reflect the goodness of the input data. Various selection schemes have been proposed (Benediktsson et al., 1997); nevertheless, the approach still remains computationally relatively complex.

Applications that use simple voting strategies like majority voting and complete agreement are both computationally less complex and able to provide promising results in terms of the classification accuracy. For example, in Benediktsson and Kanellopoulos (1999), a statistical classifier and a neural network were trained parallelly on the same data set. The different sources of a multisensor data set, consisting of multispectral and SAR imagery, were classified individually by a statistical classifier and the neural network, and the results were combined by several voting schemes. In cases where the two classifier outputs disagree, a training sample is rejected and used for the training of a second neural network. In doing so the classification accuracy was significantly increased. However, the requirement of a relatively large training sample set may be considered as a drawback of this method.

Contrary to voting or rejection schemes, in other studies an additional classifier was applied to the individual outputs, to combine the output of the previous classifiers (e.g., Waske and Benediktsson, 2007). In a first processing step, two data sets (i.e., SAR and multispectral) were classified by individual SVM, providing distances between each pixel and the separating decision function (i.e., hyperplane). Afterward an additional SVM was applied on these outputs. The proposed strategy outperforms the fusion with conventional voting schemes as well as a single SVM applied to the full data set or other parametric and nonparametric methods (i.e., maximum likelihood, decision tree, boosted decision tree) as well as two different voting schemes. Besides, the results clearly show the advantage of multisensor imagery in regard to the classification accuracy, which was improved irrespective of the classifier algorithm and training data. In Waske and van der Linden (2008), the approach was further extended by a multilevel component, which enables the inclusion of different segmentation scales of the input imagery. In doing so the classification accuracy was further increased compared to a pixel-wise classification and classifications, which are based on a single segmentation level.

In Udelhoven et al. (2009), the approach was successfully applied to hypertemporal data, consisting 10 day maximum-value NDVI composites from the "Mediterranean Extended Daily One-km Advanced Very High Resolution Radiometer Data Set" (MEDOKADS). Individual SVM classifiers were trained on normalized difference vegetation index (NDVI) time-series and mean annual temperature values of three consecutive years. Afterward the preliminary SVM outputs were fused using an

additional SVM. Compared to other simple voting strategies and a single SVM, which is trained for the same multiannual periods, the classification accuracy and robustness was increased by the proposed method. Moreover, it was demonstrated that considering the interannual variability of the annual vegetation-growth cycle improves the classification accuracy.

Summary

In this entry on decision fusion for classification of multisource remote sensing data, a brief definition on data fusion and an overview of multisource remote sensing applications was given. Examples of how approaches, which are based on decision fusion, can be applied to currently typical remote sensing data sets were presented.

In general, these studies show that the accuracy of remote sensing land cover classifications is increased due to the rapid development of EO systems, resulting in the availability of multitemporal, multisource, or high-dimensional data sets on the one hand and the use of adequate classification approaches on the other. Recent approaches, for example, based on decision fusion, enable the handling of such complex data sets efficiently and in a robust manner. Problems that occur due to limitations of traditional methods can be avoided, and results are consequently more accurate.

A higher number of diverse EO instruments and further enhancement of these systems is expected for the future. Therefore, appropriate data fusion and classification of multisource data is an important ongoing research topic in the field of remote sensing. The methodological development outlined in this entry is an alternative direction to continue.

EARTH RADIATION BUDGET, TOP-OF-ATMOSPHERE RADIATION

Bing Lin
NASA Langley Research Center, MS 420, Hampton,
VA, USA

Synonyms

Extraterrestrial radiation; Longwave radiation; Shortwave radiation; Solar radiation; Terrestrial radiation; Thermal radiation

Definition

1. Extraterrestrial radiation: the radiative energy that radiates into the Earth's climate system from the space.
2. Terrestrial radiation: the radiative energy emitted by the Earth's climate system.

Introduction

The radiation at top of the atmosphere (TOA) is the only energy exchange process between the Earth and space for the Earth's climate system. The incoming extraterrestrial radiation, dominantly from the sun, is the driving forcing for the general circulation of the climate system. In response to this solar radiative forcing, the climate system releases heat to the space through terrestrial thermal emission. For the Earth, the incoming solar radiation is generally balanced by the outgoing thermal radiation at TOA at the annual and longer timescales to maintain the climate system in a quasi-equilibrium state. Some anthropogenic processes, such as the continuous increase of the CO₂ concentration within the atmosphere caused by the increased fossil fuel burning, inject extra thermal radiative forcing into the climate system, which breaks the basic radiation balance and forces the climate to change. Since the coupling of solar and thermal radiative energy

processes with the Earth's hydrological processes such as precipitation and evaporation builds a fundamental aspect of the global water and energy cycle of the climate system, variations in radiative fields would cause corresponding changes in global precipitation patterns and freshwater distributions and have a strong social-economical impact. The observations of TOA radiation, thus, become a critical part of the remote sensing of the Earth's climate system.

The top-of-the-atmosphere radiation

Satellite direct measurements of TOA radiation (Barkstrom et al., 1989; Wielicki et al., 1996) focus on broadband spectra of the total (0.2 ~ 100 μm), shortwave (0.2 ~ 5 μm), and longwave (5 ~ 100 μm) radiation, which cover more than 99.5 % of the Earth's radiant energy. Absolute calibration and long-term stability are the core elements emphasized by satellite TOA radiation-measuring missions. Both wide and narrow field of view (FOV) techniques have been used in satellite TOA radiation measurements for decades (Barkstrom et al., 1989; Wielicki et al., 1996). Although wide FOV observations can obtain the information of global net radiation, detailed radiative transfer processes for regional and small-scale phenomena such as clouds and aerosols cannot be measured. The narrow FOV measurements, on the other hand, have reasonable spatial resolution in monitoring all large, regional, and small-scale physical processes. But to obtain the full radiant energy of these physical processes, a series of complicated satellite retrievals is required for narrow FOV radiance measurements. Each instantaneous satellite observation of the Earth's radiation field from narrow FOV broadband radiation instruments can only measure the radiance at a particular viewing angle of the targeted scene, and each scene type has its distinct three-dimensional (3-D) radiation features. In order to retrieve the radiative flux of the targeted scene from the radiance

measurement at the particular viewing angle, a 3-D angular dependent model (ADM) of radiance field for the scene type has to be used. The ADM is built from the statistics of large amounts of observational multi-angle radiance data. Thus, the spatial resolution of radiation measurements should be both large enough to satisfy the 3-D radiation statistics of individual scene types and fine enough to determine the radiative characteristics of major climate processes. Satellite radiation sensors, such as those from the Earth Radiation Budget Experiment (ERBE) (Barkstrom et al., 1989) and Clouds and the Earth's Radiant Energy System (CERES) (Wielicki et al., 1996), normally have a spatial resolution from 10 to 40 km and generally not only measure the fluxes of total, shortwave, and longwave radiation at TOA but also differentiate the radiation from individual Earth's scene types, such as clouds, aerosols, clear skies, deserts, grasses, forests, and ice sheets. Temporal resolutions of satellite radiation measurements depend on both satellite orbits and scan patterns of radiation sensors. Precession orbits can provide radiative flux measurements of broad solar incident angles for each place and scene type but usually have low repeating sampling rate. Polar orbital sensors, on the other hand, have high repeating rates of measurements for similar weather and climate conditions, but their measurements are only available for limited local times.

Another way in satellite estimations of TOA radiant energy is to observe the radiative properties of all critical agents and components within the atmosphere and at surfaces through satellite narrowband radiation measurements such as those from passive and active visible, infrared, and microwave remote sensing techniques and then to calculate the radiant energy based on these radiative properties using radiative transfer theories. The spatial and temporal resolutions of these radiative flux estimates, thus, depend on their corresponding narrowband satellite measurements, which have a wide range of variations. As the methods of satellite direct broadband radiation measurements, this indirect measurement method has also been used for decades (Rossow and Schiffer, 1999) and is a major part of the satellite remote sensing of global radiation budgets.

Satellite radiative energy measurements track all important physical processes within the Earth's climate system and are currently one of the keys in monitoring and understanding of the climate system. Climate data records from the satellite TOA radiation measurements capture global, regional, and small-scale signatures of the climate variability and change and exhibit distinct features of the tropics and polar regions in response to global warming trends. These TOA radiation measurements, especially those for cloudy and clear skies, also provide strong energy constraints for global climate models (GCMs) and lead advanced GCM cloud parameterizations. With the continuous, long-term radiation observations from CERES and other satellite radiation missions, an improved projection of future climate could be obtained.

Summary

Satellite measurements of the Earth's radiation budget have significant influences on the understanding of aerosols, cloud feedbacks, and atmospheric dynamics as well as other major climate physical processes and are critical for validations and improvements of climate models. Continuous, long-term radiation observations from satellite missions would lead to accurate predictions of the future climate.

EARTH SYSTEM MODELS

Andrea Donnellan
 Science Division, Jet Propulsion Laboratory, California
 Institute of Technology, Pasadena, CA, USA

Definition

Earth system. Various parts of the Earth that interact with each other.

Models. A representation, either physically, graphically, or using a computer, of a scientific process or phenomenon developed for providing understanding of the real process or phenomenon.

Earth system model. A representation through graphics, computer software, or physically of interacting parts of the Earth developed to provide improved understanding.

Introduction

The solid Earth includes the core, mantle, lithosphere and crust, and the cryosphere consisting of ice sheets and glaciers. The core is liquid with a solid middle and generates our Earth's magnetic field. The mantle is made of hot rock

that convects, driving plate tectonics in the lithosphere and crust. Earthquakes and volcanoes occur as a result of plate tectonics. The ice masses that make up the cryosphere interact with the solid Earth, oceans, and atmosphere.

Satellite observations are used to probe characteristics of the solid Earth from the outer liquid core to the Earth's surface.

Core

The Earth's core is made up of a solid inner core and a liquid outer core. The outer core is composed of a liquid metal alloy and forms a layer 2,260 km thick. The electrically conducting liquid metal alloy rotates and convects, generating the Earth's magnetic field. The motions within the liquid outer core vary, resulting in both long-term and short-term changes in the magnetic field of the Earth. The Earth's magnetic dipole or north and south poles are generated from the outer core and change slowly, resulting in magnetic reversals that occur on timescales of millions of years. Shorter-term variations are superposed on the long-term variations.

Measurements of the magnetic field provide a way of probing the properties of the flow in the outer core. It is necessary to separate out the magnetic field from the magnetized rocks in the Earth's crust, electrical currents from the ocean, atmosphere, and ionosphere, as well as external fields. Measurements that have been carried out over the last 150 years indicate that the Earth's magnetic field has decayed by 10 %, consistent with an ongoing reversal of the magnetic poles. The bulk of the decay is occurring at the South Atlantic Ocean. Remote sensing can detect magnetic variations on the order of 1 year, which provides information on how the fluids move within the outer core. Remote sensing measurements can also further separate the internal and external processes that generate the Earth's magnetic field. Understanding the motion of the fluids in the outer core will result in a better understanding of the motions of the oceans and atmospheres and their circulation by allowing that contribution to be separated out from the observed total angular momentum budget of the Earth.

Mantle

The mantle is a layer about 2,900 km thick between the core and the crust. The mantle is composed primarily of crystalline silicate rock, which is hot and also convects. Seismic data and gravity data collected by remote sensing indicate that there is a discontinuity in material at about 400–670 km, which marks the boundary between the upper and lower mantle. The seismic waves are deflected by the discontinuity. Scientists predict the gravitational field of the Earth based on what they know about the distribution of densities, and they then compare their prediction to ground- and/or space-based measurements of the gravitational field of the Earth. Gravity anomalies are the differences between the observed and predicted gravity field. The convection of the mantle results in varying mass

distributions throughout the mantle. Gravity anomalies have been used to show that the viscosity of the mantle increases dramatically at the boundary between the upper and lower mantle, suggesting that convection occurs in the upper mantle separately from the lower mantle.

The asthenosphere makes up the upper part of the mantle and is about 200 km thick. The rocks in the asthenosphere flow readily and are typically made up of olivine. The lithosphere, which is marked at the bottom by the transition from ductile to brittle olivine, makes up the very top of the mantle and the lower part of the Earth's crust and is made up of rigid rocks. Convection of the mantle drives plate tectonics and molten rock from the mantle, comes to the surface by way of volcanoes, and spreads ridges between the tectonic plates.

Lithosphere and crust

The rigid lithosphere is typically 50–200 km thick under the oceans and is up to 200 km thick under the continents. The Earth's crust is found in the top 30–50 km of the lithosphere over continents. The chemical composition of the rocks changes in the crust, and the base is marked by the Moho discontinuity, determined from seismology.

Plate tectonics

The mantle convection that drives plate tectonics creates convergent zones, where one plate subducts under another plate, transform, and extensional zones. Transform plate boundaries are typically found in the ocean but can also occur on land, such as in California. Extension is typically found at spreading ridges in the ocean. Hot spots, which are upwellings of hot material from deep in the mantle, can also cause spreading in the crust. The Basin and Range Province in the Western United States is an example of spreading induced by a hot spot. Volcanoes with different characteristics can form over hot spots, spreading centers, and subduction zones.

Seismology has been used extensively to understand earthquakes as well as characteristics of the solid Earth and of volcanoes. The advent of remote sensing has allowed for the measurement of surface motions to millimeter precision. This makes it possible to measure plate tectonics, comparing the rates to those determined through other geologic techniques. Measurement of surface deformation yields information about the material properties such as strengths and rigidity of the lithosphere and mantle and provides insight into the complete strain accumulation and release related to earthquakes and volcanoes.

Earthquakes

Earthquakes occur in the brittle part of the crust and mantle. They occur when stress increases, typically from motion due to the tectonic plates, and exceeds a threshold, at which point the crust breaks. The resulting shaking is an earthquake, which can be measured through the use of seismometers. However, the earthquake makes up only a small part of the entire earthquake cycle of strain

accumulation and release. Earthquakes typically occur along faults that have broken many times in the past. They are associated with convergent, transform, and extensional plate tectonics. There are three major types of faults, which are thrust, strike-slip, and normal faults.

Thrust faults and thrust earthquakes occur where the crust is shortening or converging. In these types of earthquakes, one block slides up over the bottom block along a fault oriented diagonally from depth toward the surface. Thrust earthquakes typically occur at subduction zones but can also occur where there is mantle downwelling or plate collision underneath the crust. Subduction zones are found along the margins of the Pacific plate along the coasts of South America, the Pacific Northwest of the United States, Canada, and Alaska, and underneath Japan. A prime example of a collision zone is the Himalayas. The thrust earthquakes in Southern California are associated with a downwelling underneath the Transverse Ranges.

Strike-slip earthquakes result when one side of a fault slips horizontally in either direction on both sides of a fault. Strike-slip faults occur along transform boundaries that offset spreading centers along divergent plate boundaries. The San Andreas Fault in California is a major strike-slip fault and makes up the primary boundary between the Pacific and North American Plates. The actual plate boundary is about 100 km wide, however.

Normal faults occur in regions where extension is occurring. A normal fault is also oriented diagonally from the upper part to the lower part at depth, but in this case, the upper block moves down and away relative to the lower block along the fault. The Basin and Range Province of the Western United States produces many normal faults. As the crust stretches, blocks in the valley, known as grabens, move down. The mountains move upward and are referred to as horsts.

Various techniques can be used to measure the strain associated with the earthquake cycle. Ground-based observations provided measurement of strain. The Global Positioning System (GPS) is now used to measure surface deformation at mm/year accuracy around the globe. The measurements provide time continuous precise measurements at distinct points. Another technique, called interferometric synthetic aperture radar (InSAR), relies on radar waves transmitted from a satellite and reflected back to the satellite from the Earth's surface. When the satellite exactly repeats its track, then differences in the radar return are due to surface motions, as well as error sources. The two observations are coupled together and form an interferogram where the radar waves interfere due to the surface motions. InSAR provides a precise map of deformation of the Earth's surface to/from the satellite.

Faults typically creep at depth, where the crust or mantle is hotter, and are locked at the surface except for when they break in earthquakes. The brittle part of the upper crust behaves elastically and moves in a predictable manner when strained. Observations of surface deformation yield information about the entire earthquake cycle, the

cycle of strain accumulation and release, and provide information about fault activity and slip rates.

Recent work using remote sensing has demonstrated that silent slip events that mimic earthquake slip without the shaking are fairly common. Additionally a substantial amount of continued motion, referred to as postseismic response, can occur following earthquakes. The postseismic motions can result from relaxation of the more ductile lower crust or continued slip on the main fault plane. Models that incorporate seismic and crustal deformation are providing a system level understanding of earthquake processes and are improving assessments of earthquake hazards.

Volcanoes

Volcanoes are ruptures at the Earth's surface that allow magma and gases to escape from the Earth's interior. There are three primary types of volcanoes associated with divergent and convergent plate boundaries and hot spots. At spreading centers associated with divergent plate boundaries, the crust is typically thin, and the magma is of low viscosity and basaltic, coming from melted mantle. Subduction zone volcanoes associated with divergent plate boundaries tend to be explosive as the high-silicate-content subducting crust is heated and rises. A rising plume from a mantle hot spot also creates volcanoes. In cases such as Hawaii, chains of volcanoes form as the tectonic plate moves over the relatively fixed hot spot.

Magma moving beneath the surface of the Earth causes the surface of the Earth to deform and change temperature. GPS and interferometric radar (InSAR) are used to measure surface deformation, while short-wavelength infrared data are used to measure thermal characteristics of the surface. These observations are used to infer the location and migration of magma at depth, which are then used to determine the activity of a volcano and likelihood of eruption.

Cryosphere

Ice masses covering the Earth make up the cryosphere. This includes ice sheets, glaciers, and sea ice. The cryosphere has shown tremendous variability in the geologic record. The components of the cryosphere are sensitive to inputs and thermal exchanges from the atmosphere, ocean, and solid Earth. Volcanoes, hot spots, and subsurface topography, and geology at the base can control behavior of ice masses that overlie them. Ocean sea level and temperature affect the margins of ice sheets, which can lead to changes in the interiors. Changes in atmospheric temperature and precipitation can also modify ice sheet behavior. Remote sensing can be used to understand long-term ice sheet and glacier records as well as present-day ice dynamics.

Glacio-isostatic adjustment

Ice sheets depress the crust and mantle that underlie them. As ice sheets thicken, the surface of the rock is depressed downward, flexing the crust beyond the extent of the ice

sheet. When ice sheets thin, the opposite occurs and the crust and mantle rebound. However, the mantle is viscous and as a result has a delayed response for complete rebound. Knowing the mantle viscosity allows inferences to be made about past ice sheet history. Conversely, understanding ice sheet history can provide insight into mantle viscosity.

GPS measurements provide the rates and distribution of present-day glacio-isostatic adjustment. Time-varying gravity measurements from space indicate locations of mass changes, which can be related to glacio-isostatic adjustment. These measurements are used in Earth system models to understand past ice sheet history and crust and mantle properties.

Ice sheet dynamics

Ice sheets are quite variable on short timescales as well as on long timescales. The mass balance of an ice sheet refers to whether the ice sheet is thickening or thinning (losing or gaining mass). Understanding the mass balance of ice sheets requires knowledge of the thickness changes of the ice sheet, but also the flow rates of the ice sheet. Repeat altimetry, such as laser altimetry from LIDAR (Light Detection and Ranging), informs scientists regarding height changes of the ice sheet, which can be translated to thickness changes. Adding in flow measured from GPS or InSAR allows for a complete measurement of the volume changes of the ice sheet. Flow can also be inferred from tracking features in visible images. It is also possible to observe where the changes are occurring and whether those changes are migrating with time. For example, the Greenland ice sheet measurements indicate that the thinning started near the coast and is migrating inland, suggesting that ocean changes are a bigger driver than atmospheric changes. Earth system models take into account the basal characteristics of the ice sheet, flow and thickness parameters, as well as ocean and atmospheric coupling.

Ice shelves floating on the margins of ice sheets can be quite unstable. Radar and other imagery can be used to observe breakup of ice shelves as it occurs. The breakup of ice shelves also needs to be factored into flow models of the adjacent ice sheet.

Sea ice

Changes in sea ice cover provide indicators of how the climate is changing and also impacts shipping lanes. Radar and other imagery can be used to track sea ice flow, coverage characteristics, and floe distributions. Altimetry, such as from LIDAR, can be used to estimate the sea ice freeboard, or the amount of sea ice floating above the surface. Passive microwave remote sensing is used to measure the thermal, dielectric, and geophysical properties of snow on the sea ice. The measured parameters coupled with models show the annual evolution of the Arctic sea ice, atmosphere, and ocean system.

Conclusions

The solid Earth functions as a system, ranging from the core through the mantle to the crust and cryosphere. The geodynamo operating within the core provides the Earth's magnetic field, which varies due to flow within the core. The mantle interacts with and is a key component of plate tectonic, earthquake, and volcanic systems, and earthquakes and volcanoes result from plate tectonics. The cryosphere also interacts with the crust and the mantle depressing the solid Earth surface due to the mass of ice sheets. Tectonic plate motions can in turn affect ice sheets. It is important to model the Earth as a system in order to separate out different effects and to understand the individual components of the system.

Remote sensing offers a way of probing various components of the solid Earth, providing key parameters to Earth system models. The mechanisms that drive various solid Earth processes primarily occur underneath the surface and as such are not directly observable. Furthermore, remote sensing provides a regional view that is more difficult to obtain with in situ measurements.

Acknowledgments

This research was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the NASA.

ELECTROMAGNETIC THEORY AND WAVE PROPAGATION

Yang Du

Zhejiang University, Hangzhou, People's Republic of China

Definition

Electromagnetic theory. Theory based on the Maxwell equations to study the properties and dynamics of electromagnetic fields.

Wave propagation. The process of transporting electromagnetic energy.

Maxwell equations

The Maxwell equations lay the foundation of all classical electromagnetic phenomena. They describe how time-varying electric fields give rise to magnetic fields and vice versa. The Maxwell equations are a set of four equations

$$\nabla \cdot \mathbf{D} = \rho \text{ (Coulomb's law)}$$

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \text{ (Faraday's law)} \quad (1)$$

$$\nabla \times \mathbf{H} = \frac{\partial \mathbf{D}}{\partial t} + \mathbf{J}$$

(Ampere's law with displacement current addition)

$$\nabla \cdot \mathbf{B} = 0 \text{ (Absence of free magnetic poles)}$$

The six quantities in terms of which the electromagnetic field equations are expressed are as follows:

- $\mathbf{D}$ = Electric flux density or electric displacement (coulombs per square meter)
- $\mathbf{E}$ = Electric intensity (volts per meter)
- $\mathbf{B}$ = Magnetic flux density (Weber's per square meter)
- $\mathbf{H}$ = Magnetic intensity (amperes per meter)
- $\mathbf{J}$ = Electric current density (amperes per square meter)
- ρ = Electric charge density (coulombs per cubic meter)

In vacuum $\mathbf{D} = \epsilon_0 \mathbf{E}$ and $\mathbf{B} = \mu_0 \mathbf{H}$, where $\epsilon_0 \approx 8.85 \times 10^{-12}$ farad/m is the permittivity, and $\mu_0 = 4\pi \times 10^{-7}$ Henry/m is the permeability. The continuity equation for charge density and current density can be derived from the above Maxwell equations

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \mathbf{J} = 0 \quad (2)$$

When electromagnetic wave propagates in some medium other than vacuum, since the characteristic wavelength is very large compared to the atoms of which the medium is composed, the detailed behavior of the fields over atomic distance can be neglected. What are relevant are the quantities averaged over the atomic scale, including the macroscopic fields and macroscopic

sources. The constitutive relations, which relate $\mathbf{D}$ and $\mathbf{B}$ to $\mathbf{E}$ and $\mathbf{H}$, may take forms much more complicated than those in vacuum (see [Media, Electromagnetic Characteristics](#)).

Boundary conditions

Maxwell equations in the form of [Equation 1](#) concern ordinary points of space in whose neighborhood the physical properties of the medium vary continuously. However, at boundary of two different media, the permittivity, permeability, and conductivity can change sharply. The discontinuous change on a macroscopic scale will lead to corresponding discontinuity in the field vectors. The discontinuity equations are collectively called boundary conditions (Jackson, 1998; Kong, 2005).

The boundary conditions for the normal components of the electric flux density $\mathbf{D}$ and magnetic flux density $\mathbf{B}$ on either side of the boundary surface are

$$\begin{aligned} (\mathbf{D}_1 - \mathbf{D}_2) \cdot \hat{n} &= \sigma \\ (\mathbf{B}_1 - \mathbf{B}_2) \cdot \hat{n} &= 0 \end{aligned} \quad (3)$$

where the normal $\hat{n}$ is pointing from medium 1 into medium 2, σ is an idealized surface current density that is related to the charge density ρ singular at the interface by $\int_{\Delta V} \rho dv' = \sigma \Delta s$, and ΔV is an infinitesimal

pillbox of area Δs and height Δh , with half of its volume in each medium and its top and bottom parallel to the surface. [Equation 3](#) states that at any point on the boundary the normal component of $\mathbf{B}$ is continuous, while that of $\mathbf{D}$ is discontinuous with the discontinuity equal to the surface charge density.

The boundary conditions for the tangential components of $\mathbf{E}$ and $\mathbf{H}$ on either side of the boundary surface are

$$\begin{aligned} \hat{n} \times (\mathbf{E}_2 - \mathbf{E}_1) &= 0 \\ \hat{n} \times (\mathbf{H}_2 - \mathbf{H}_1) &= \mathbf{J}_s \end{aligned} \quad (4)$$

where $\mathbf{J}_s$ is an idealized surface current density flowing on the boundary surface which satisfies the condition $\int_{\Delta S} (\frac{\partial \mathbf{D}}{\partial t} + \mathbf{J}) \cdot \hat{t} ds = \hat{t} \cdot \mathbf{J}_s \Delta l$ and ΔS is an open surface

spanning an infinitesimal contour of line Δl parallel to the surface, with half of its area in each medium and its normal $\hat{t}$ tangent to the surface. [Equation 4](#) states that at any point on the boundary the tangential component of $\mathbf{E}$ is continuous, while that of $\mathbf{H}$ is discontinuous by an amount of identical magnitude with direction parallel to $\mathbf{J}_s \times \hat{n}$.

Scalar and vector potentials

Potentials are useful auxiliary functions in analysis of an electromagnetic field. This is because coupling between the electric and magnetic fields in the Maxwell equation makes direct solution difficult, except in simple situations. Potentials, however, if introduced properly, can lead to decoupled equations of their own while identically

satisfying some of the Maxwell equations. The potentials commonly introduced are the scalar potential ϕ and vector potential $\mathbf{A}$ (Jackson, 1998; Kong, 2005).

Since the magnetic flux density $\mathbf{B}$ is always solenoidal, i.e., $\nabla \cdot \mathbf{B} = 0$, it can be represented as the curl of the vector potential $\mathbf{A}$.

$$\mathbf{B} = \nabla \times \mathbf{A} \quad (5)$$

This representation, together with Faraday's law, implies that the electric intensity $\mathbf{E}$ can be expressed in terms of the scalar and vector potentials as

$$\mathbf{E} = -\nabla\phi - \frac{\partial \mathbf{A}}{\partial t} \quad (6)$$

Consider the case where the medium is homogeneous and isotopic, for which the constitutive relations are $\mathbf{D} = \epsilon \mathbf{E}$, $\mathbf{B} = \mu \mathbf{H}$. The arbitrariness of choice of $\mathbf{A}$ inherent in [Equation 5](#) and of ϕ through [Equation 6](#) allows the choice of a set of potentials $(\mathbf{A}, \phi)$ to satisfy the Lorenz condition,

$$\nabla \cdot \mathbf{A} + \mu\epsilon \frac{\partial \phi}{\partial t} = 0 \quad (7)$$

Making use of the remaining two Maxwell equations leads to two inhomogeneous wave equations, uncoupled for ϕ and $\mathbf{A}$ as

$$\begin{aligned} \Delta^2 \phi - \mu\epsilon \frac{\partial^2 \phi}{\partial t^2} &= -\frac{\rho}{\epsilon} \\ \Delta^2 \mathbf{A} - \mu\epsilon \frac{\partial^2 \mathbf{A}}{\partial t^2} &= -\mu \mathbf{J} \end{aligned} \quad (8)$$

These equations, equivalent to the Maxwell equation in all respect in a homogeneous and isotopic medium, can be conveniently analyzed using the Green's function.

Green's function for the wave equation

The underlying structures are identical for the wave equations (Jackson, 1998)

$$\nabla^2 \psi - \mu\epsilon \frac{\partial^2 \psi}{\partial t^2} = -f(\mathbf{r}, t) \quad (9)$$

with $f(\mathbf{r}, t)$ being a known source distribution. After Fourier transform, $\psi(\mathbf{r}, \omega)$ satisfies the inhomogeneous Helmholtz wave equation

$$(\nabla^2 + k^2)\psi(\mathbf{r}, \omega) = -f(\mathbf{r}, \omega). \quad (10)$$

The corresponding Green's function $g(\mathbf{r}, \mathbf{r}')$ satisfies the inhomogeneous equation

$$(\nabla^2 + k^2)g(\mathbf{r}, \mathbf{r}') = -\delta(\mathbf{r} - \mathbf{r}') \quad (11)$$

where $\delta(\mathbf{r})$ is the Dirac delta function. In an unbounded medium, the Green's function is

$$g(\mathbf{r}, \mathbf{r}') = \frac{e^{ik|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} \quad (12)$$

where $k = \omega\sqrt{\mu\epsilon}$ is the wave number in the medium and $|\mathbf{r} - \mathbf{r}'|$ is the distance between the field point $\mathbf{r}$ and the source point $\mathbf{r}'$. This form of Green's function represents a diverging spherical wave propagating from the origin.

The above Green's function is the scalar Green's function because it relates scalar field to scalar source. If both field and source are vectors, dyadic Green's function must be used instead which satisfies the inhomogeneous equation (Kong, 2005)

$$\nabla \times \nabla \times \bar{\bar{G}}(\mathbf{r}, \mathbf{r}') - k^2 \bar{\bar{G}}(\mathbf{r}, \mathbf{r}') = \bar{\bar{I}}\delta(\mathbf{r} - \mathbf{r}') \quad (13)$$

where $\bar{\bar{I}}$ is the identity dyad. The dyadic Green's function can be expressed in terms of the scalar Green's function as

$$\bar{\bar{G}}(\mathbf{r}, \mathbf{r}') = \left[\bar{\bar{I}} + \frac{1}{k^2} \nabla \nabla \right] g(\mathbf{r}, \mathbf{r}') \quad (14)$$

Poynting's theorem and conservation of energy

Poynting's theorem is a law of conservation of energy for the electromagnetic field. From the Maxwell equations, considering the fields in a finite volume V , the following equation can be readily established (Jackson, 1998):

$$-\int_V \mathbf{J} \cdot \mathbf{E} dv' = \int_V \left[\nabla \cdot (\mathbf{E} \times \mathbf{H}) + \mathbf{E} \cdot \frac{\partial \mathbf{D}}{\partial t} + \mathbf{H} \cdot \frac{\partial \mathbf{B}}{\partial t} \right] \quad (15)$$

Each term of the above equation has physical meaning. The left side of the equation represents the negative of the total work done by the fields on the sources within the volume. Integral of the first term on the right side of the equation represents the energy that flows out of the volume through the boundary surfaces per unit time. Since energy flow is such an important concept, to represent it a vector $\mathbf{S}$ is specifically defined which is called the Poynting vector given by

$$\mathbf{S} = \mathbf{E} \times \mathbf{H}. \quad (16)$$

The last two terms on the right side are collectively associated with the total energy density u (electric and magnetic energy density combined) for a linear medium with negligible dispersion or losses. To be specific, they are the time rate of change of the total energy density, i.e., $\frac{\partial u}{\partial t}$. Integral of the last two terms is then the time rate of change of electromagnetic energy within a certain volume. Equation 15 is a statement of conservation of energy; the diminution of electromagnetic energy stored in V is partly due to electromagnetic energy flows outward across the boundary surfaces and partly due to a conversion of electromagnetic energy into mechanical or heat energy.

For more general case of linear dispersive media, interpretation of the right side of Equation 15 is more involved.

For harmonic electromagnetic fields, it is more convenient to use the complex Poynting vector given by $\mathbf{S} = \frac{1}{2}(\mathbf{E} \times \mathbf{H}^*)$.

Plane wave

Plane waves are the simplest and fundamental electromagnetic waves. All wave functions can be expressed as superpositions of plane waves. In an unbounded uniform isotropic linear media, where $\mathbf{D} = \epsilon\mathbf{E}$, $\mathbf{B} = \mu\mathbf{H}$, the harmonic plane wave fields are

$$\begin{aligned} \mathbf{E}(\mathbf{r}, t) &= \mathbf{E}e^{i\mathbf{k} \cdot \mathbf{r} - i\omega t} \\ \mathbf{H}(\mathbf{r}, t) &= \mathbf{H}e^{i\mathbf{k} \cdot \mathbf{r} - i\omega t}, \end{aligned} \quad (17)$$

which satisfy the homogeneous Helmholtz wave equation. The Maxwell equations demand that both $\mathbf{E}$ and $\mathbf{H}$ are perpendicular to the vector $\mathbf{k}$. If $\mathbf{k}$ is real, then it can be written as $\mathbf{k} = k\hat{\mathbf{k}}$, where $k = \omega\sqrt{\mu\epsilon}$ is the wave number and $\hat{\mathbf{k}}$ is a real unit vector indicating the direction of propagation. If $\mathbf{k}$ is complex, then it is expressed through two real vectors as $\mathbf{k} = \beta + i\alpha$, and the plane wave represented by Equation 17 propagates in the direction of β and attenuates in the direction of α (Harrington, 1961).

If the media are semi-infinite with different properties separated by a plane surface, then at the interface electromagnetic waves experience reflection and refraction. Angle of reflection θ_r equals angle of incidence θ_i , while angle of refraction θ_t is determined by Snell's law, which states that the ratio of sine of angle of refraction to sine of angle of incidence equals the ratio of index of refraction n in the medium of incidence to index of refraction n' in the medium of transmission. The Fresnel reflection coefficient, which specifies the ratio of the reflected electric intensity to the incident electric intensity, depends on how the electric field is directed. If the electric field is perpendicular to plane of incidence, then the Fresnel reflection coefficient is (Jackson, 1998)

$$R_{\perp} = \frac{\cos \theta_i - \frac{\mu}{\mu'} \frac{n'}{n} \cos \theta_t}{\cos \theta_i + \frac{\mu}{\mu'} \frac{n'}{n} \cos \theta_t} \quad (18)$$

where μ and μ' are the permeability in the medium of incidence and of transmission, respectively. If the electric field is parallel to plane of incidence, then the Fresnel reflection coefficient is

$$R_{//} = \frac{\frac{\mu}{\mu'} \frac{n'}{n} \cos \theta_i - \cos \theta_t}{\frac{\mu}{\mu'} \frac{n'}{n} \cos \theta_i + \cos \theta_t}. \quad (19)$$

There is an important aspect associated with this case; when angle of incidence equals Brewster's angle, there is no reflected wave. Brewster's angle can be simply determined by $\theta_B = \tan^{-1}(\frac{\mu}{n})$ when $\mu = \mu'$.

If index of refraction in the medium of incidence is larger than that in the medium of refraction, the phenomenon called total internal reflection can occur when there is no energy flow across the surface.

Electromagnetic wave scattering from randomly rough surfaces

Electromagnetic wave scattering from randomly rough surfaces is fundamental to geophysics, terrestrial, and extraterrestrial remote sensing, and wireless and satellite communications. This field is a rich and active research area, and it has become impossible to cover all recent advances in analytical approaches here. The readers are referred to earlier general survey papers or books on analytical models (Elfouhaily and Guerin, 2004; Fung, 1994; Tsang et al., 1985; Ulaby et al., 1982).

The complex character of electromagnetic wave interaction with rough surface may require different classes of models in different situations. A qualitative sketch of regions of validity for analytical models is shown in Figure 1. For the region where the RMS height is very small compared to the wavelength, the small perturbation method (SPM) is applicable, which is derived rigorously from the extended boundary condition without resorting to any a priori assumption about the field. For the region where surfaces have large surface curvatures, the Kirchhoff approximation (KA) is commonly used. It is a local approximation in that it uses tangent plane approximation by assuming the surface field to be generated as if a tangent plane were at the same point while ignoring the contribution from the surface elsewhere. In the high-frequency regime, by invoking stationary phase method, the scattered amplitude reduces to a probability density function of slopes that are evaluated at specular points. In this case KA is also called the geometrical optics (GO) method. For the regions in between, there are active ongoing researches in seek of so-called unifying methods. In the survey by Elfouhaily and Guerin (Elfouhaily and Guerin, 2004), these unifying methods are classified into generic families, including the Meecham-Lysanov method, the phase perturbation method (PPM), the small slope approximation (SSA), the operator expansion method (OEM), the tilt invariant approximation (TIA), the local weight approximation (LWA), the Wiener-Hermite approach, the unified perturbation expansion (UPE), the full wave approach (FWA), the improved Green's function methods, the volumetric methods, and the integral equation method (IEM). Considering the wide use of the IEM model in the analysis of scattering from terrestrial rough surfaces on the one hand and the presentation of IEM and its related models in (Elfouhaily and Guerin, 2004) being very brief or barely touched on the other hand, these models will be elaborated a bit here to shed more light into their respective strength and limitations so as to help the practitioner make more intelligent choice.

The original IEM model (Fung, 1994) has shown to provide good predictions for forward and backward scattering coefficients. To make the derivation of the IEM model mathematically tractable, several assumptions were made, which include the following (Chen et al., 2003):

Electromagnetic Theory and Wave Propagation,

Figure 1 Qualitative sketch of regions of validity for the rough surface scattering models.

1. Spatial dependence of the local incident angle of the Fresnel reflection coefficient is removed, by either replacing it with the incident angle or the specular angle.
2. For the cross-polarization, the reflection coefficient used to compute the Kirchhoff fields is approximated by $(R_{//} - R_{\perp})/2$, where $R_{//}$ and $R_{\perp}$ are the Fresnel reflection coefficients of transverse magnetic and transverse electric waves, respectively.
3. Edge diffraction terms are excluded.
4. Complementary field coefficients are approximated by simplifying the surface Green's function and its gradient in the phase terms.

Concerns over the assumptions have prompted several modifications and variations of IEM in the literature. Regarding the spectral representation of the Green's function, the simplification was discarded and full form was restored, resulting in a modification to the complementary components. The resulted model is the so-called improved IEM model (I-IEM) (Hsieh and Fung, 1999). Additional restoration of the spectral representation of the gradient of the Green's function in its full form leads to the advanced IEM model (AIEM) (Chen et al., 2003) and the IEM2M model (Alvarez-Perez, 2001).

However, there are some technical subtleties in connection with the restoration of the full Green's function that have not been adequately reflected in these models. For example, in calculating the Kirchhoff-complementary incoherent power, one of the new quantities which need to be evaluated is the following:

$$I_F = \langle \exp\{-i[k_{sz}z + k_z z' - q|z - z'|]\} \rangle$$

where k_{sz} and k_z are the z -components of the scattered and incident wave vectors, respectively; q is the z -related term

in the spectral representation of the Green's function; z and z' are the heights of two points on the surface, respectively, with the surface being assumed to be a Gaussian process; and the corner brackets denote the expected value. After introducing transformation of variables, one finds that I_F contains a factor of the following form:

$$I_{F2} = \frac{1}{\sqrt{2\pi\sigma\sqrt{1-\rho}}} \times \int_{-\infty}^{+\infty} dy_2 \left\{ \exp \left\{ -i \left[\frac{k_{yz}y_2}{\sqrt{2}} - \frac{k_z y_2}{\sqrt{2}} - \sqrt{2}q|y_2| \right] \right\} \times \exp \left[-\frac{y_2^2}{2\sigma^2(1-\rho)} \right] \right\},$$

where σ is the RMS height and ρ is the surface correlation function. Due to the presence of the absolute phase term, the result on I_{F2} will contain the error function. However, all the terms related to the error function have been ignored in the above models. After inclusion of the missing terms (Du, 2008), for the cross and the complementary incoherent powers, it is shown that each consists of two terms: one free from and the other related to the error function. Moreover, for the cross incoherent power, the term free from error function appears to be identical to that reported in the literature. So the other term related to error function serves as a correction term for previous calculations. It is not the case for the complementary incoherent power: The term free from error function takes a different form from that in the literature. The reason is that the evaluation of this term is more technically involved, and certain assumptions are required to make the derivation mathematically tractable. The assumptions tacitly made in Chen et al. (2003) become more explicit in Alvarez-Perez (2001). The work in Du (2008) departs from above models in another essential way by making fewer assumptions. As a result, the new model, called the enhanced advanced IEM (EAIEM), is expected to apply to a wider range with a better accuracy. This point is at least partially verified by the comparative performance (see Figure 2).

The weakness of the conventional IEM model can be examined from another angle. Assumption (1) of IEM is an oversimplification of the statistic behavior of the unit normal $\hat{n}$ directed out of the surface at an arbitrary point $\mathbf{r}$ on the surface. Specifically, $\hat{n}$ is effectively restricted to a deterministic quantity, with the direction depending on the angles of incidence and scattering, while giving up all its statistical features. Such simplification may introduce some unwanted effect on the predictive power of the model, since the statistical features of a unit normal can be rich and strong correlations can be observed between unit normal vectors. For example, consider a randomly rough surface described by a Gaussian process with Gaussian power spectrum. If $\hat{n}$ is expressed in terms of the spherical coordinates (θ_n, ϕ_n) as $\hat{n} = \hat{x} \sin \theta_n \cos \phi_n + \hat{y} \sin \theta_n \sin \phi_n + \hat{z} \cos \theta_n$, then the azimuthal angle ϕ_n and the elevation angle θ_n are

Electromagnetic Theory and Wave Propagation,

Figure 2 Comparisons of bistatic scattering models EAIEM, AIEM, and IEM2M against measurement data for a Gaussian surface. The relative permittivity of the surface is $\epsilon_r = 5.5 + i2.2$, and the frequency is 10 GHz, leading to a normalized correlation length $kL = 12.56$ and a normalized surface RMS height $k\sigma = 0.84$. The incidence angle is fixed at $\theta_i = -20^\circ$, while the scattering angle varies from -50° to 50° .

independent random variables, where ϕ_n is uniformly distributed in the interval $[0, 2\pi]$ and the probability density function of θ_n is

$$p(\theta_n) = \frac{1}{\sigma_s^2} \exp \left(-\frac{\tan^2 \theta_n}{2\sigma_s^2} \right) \frac{\tan \theta_n}{\cos^2 \theta_n},$$

where σ_s is the RMS slope. The distribution of θ_n , unlike treated in IEM, is independent of the combination of the angles of incidence and scattering. Moreover, for two-unit normal vectors $\hat{n}$ and $\hat{n}'$ at two points on the surface, respectively, if we express them in terms of the directional partial derivatives such that $\hat{n} = \frac{-\hat{x}Z_x - \hat{y}Z_y + \hat{z}}{\sqrt{1+Z_x^2+Z_y^2}}$ and form the

four dimensional vector $\mu = [Z_x, Z_y, Z'_x, Z'_y]^t$, then μ is a multivariate Gaussian random vector with zero mean and covariance matrix C . Inclusion of the statistical behaviors of the surface unit normal vectors in conjunction with the Kirchhoff approximation in the analysis of electromagnetic scattering from a randomly rough surface was presented in Du et al. (2005). The new model was called the slope statistical Kirchhoff (SSK) model. It was shown by numerical simulations that the predictions of SSK are in better agreement with MoM results than those of the conventional Kirchhoff model (KM). A typical comparison is shown in Figure 3. One finds from this figure that besides an overall better performance, SSK appears almost immune to the Brewster angle effect for vertical polarization. This feature is expected since the directions of the unit normal which lead the local angles of incidence to approach the Brewster angle occupy only a small

Electromagnetic Theory and Wave Propagation,
Figure 3 Comparisons among MoM, KM, and SSK simulations at 6 GHz with $\epsilon_r = 3 + i0.1$, correlation length $L = 3$ cm, RMS height $\sigma = 0.429$ cm.

portion of the directional distribution; contributions from the rest of the distribution become appreciable in this new treatment.

Inclusion of the statistical behaviors of the surface unit normal vectors in combination with the IEM formulism was presented in Du et al. (2007), where the shadowing effect is also included but is not expected to have any appreciable impact on the scattering behaviors predicted by the model for the range of angles of incidence considered, which is limited to be not large (say, under 70°), a restriction inherent to the IEM formulism. The new model was called the statistical IEM (SIEM) model. It was shown by numerical simulations that the predictions of SIEM are in better agreement with MoM results than those of the IEM model.

Electromagnetic wave scattering from vegetation canopy

The potential use of microwave observations to monitor vegetation water content (VWC) and soil moisture is of great importance (e.g., Storvold et al., 2006; Singh and Kathpalia, 2007). Detection of VWC is useful to monitor vegetation stress and important for irrigation management and yield forecasting. Soil moisture is often the limiting factor in transpiration of plants and evaporation from soil surface, which in turn has a significant impact on the energy cycle. Soil moisture is also a key determinant of the global carbon cycle.

Yet to extract VWC and soil moisture from microwave observations presents a big challenge, which calls for good management of many important issues, among which are the development of a high fidelity scattering model.

In developing such scattering model, a number of factors associated with the vegetation canopy and with the underlying bare soil should be taken into account. Regarding the vegetation canopy, it is important to include the coherent effect caused by the vegetation structure at low frequencies (Zhang et al., 1995), an effect that has been well addressed in a number of recent models. For instance, the branching model due to Yueh et al. (1992) addressed the coherence effects caused by the vegetation structure, where a two-scale branching vegetation structure was used for soybeans, and the scattered fields from constituents were added coherently. A similar treatment in considering coherent effects was proposed in Lin and Sarabandi (1997) for forest canopies. Chiu and Sarabandi also considered the second-order, near-field interaction between constituents in addition to the coherence effect in their scattering model for soybean (Chiu and Sarabandi, 2000).

Yet the roughness effect of the underlying bare soil has not been adequately addressed in the above coherent models. Notarnicola and Posa, in their study of inferring VWC of corn and soybean from C- and L-band SAR images, observed that in the inversion procedure, the introduction of the dependence on roughness improves the estimates (Notarnicola and Posa, 2007). They inferred from such observation that, even for dense vegetation, the contribution from bare soil greatly influences the radar signal. To predict backscattering from the rough surface, the Kirchhoff approximation (KA) was used in Yueh et al. (1992), while a second-order small perturbation model (SPM) and a physical optic (PO) model were incorporated in Chiu and Sarabandi (2000). It is well known that the SPM model and the KA model are applicable for slightly rough surfaces and surfaces with small surface curvatures, respectively (Ulaby et al., 1982; Kong, 2005).

Regarding modeling of the vegetation, the vegetation constituents are represented by simple geometries as in Yueh et al. (1992) and Chiu and Sarabandi (2000). Specifically, stems, branches, and pods are modeled as dielectric circular cylinders of finite length. In Chiu and Sarabandi (2000) leaves are represented by elliptical thin dielectric disks, yet it was found through numerical simulation that unless ellipticity ratio is much larger than unity, the final backscatter is insensitive to the ellipticity ratio, so for simplicity leaves can be modeled as circular thin dielectric disks as in Yueh et al. (1992). The orientation distribution of the constituents is described by two angles: the elevation angle β and the azimuth angle γ , for the latter an azimuthal symmetry is assumed.

There are five major scattering mechanisms for a vegetation canopy: (1) direct backscatter from the underlying rough surface, (2) direct backscatter from soybean elements, (3) single ground bounce from scatterer to ground, (4) single ground bounce from ground to scatterer, and (5) double ground bounce. These scattering mechanisms are illustrated in Figure 4. Chiu and Sarabandi considered two additional scattering mechanisms (Chiu and Sarabandi, 2000), namely, second-order

Electromagnetic Theory and Wave Propagation,
Figure 4 Major scattering mechanisms for a vegetation canopy.

scattering interaction among vegetation constituents and scattering interaction between main stem and the rough surface. It was concluded that the latter mechanism is only considered for predicting the cross-polarized scattering at L-band (Chiu and Sarabandi, 1999). For the second-order near-field effect, good comparative illustrations with other scattering mechanisms were provided in Chiu and Sarabandi (2000) at both L- and C-band for two data sets: one from polarimetric measurements conducted using the University of Michigan polarimetric scatterometer systems (POLARSCAT) on a soybean field near Ann Arbor, MI, in August 1995, when the soybean plants were fully grown with significant numbers of pods, and the other from backscatter data collected by AIRSAR during its flight over the Kellogg Biological Station near Kalamazoo, MI, on July 12, 1995, when the soybeans were about a month old. It is observed from the decomposed contributions due to different scattering mechanisms that for not fully grown soybeans (the AIRSAR data set), contribution from rough surface is at least 25 dB higher than that from the second-order interaction for copolarized backscatter at L-band, and similar observation applies to the fully grown soybeans, so the authors concluded that the contribution from the second-order near field is negligible at L-band (Chiu and Sarabandi, 2000). At C-band, although the second-order near-field scattering is significant for fully grown soybeans as suggested by the authors, for not fully grown soybeans, contribution from rough surface is about 10 dB higher for the horizontally polarized backscatter up to 50° , while showing a cross-over with the second-order interaction for the vertically polarized backscatter at around 35° . Such observation indicates that it is more important to improve the predictive accuracy of scattering from rough surface than to include the second-order near-field effect, even at C-band, for copolarized backscatter at small to moderate incident angles. In fact, such statement may be further strengthened if one considers the fact that the estimated ground truth in Chiu and Sarabandi (2000) corresponds to a rather smooth surface, with a RMS height of 0.38 cm and a correlation length of 3.8 cm, which is several times smaller than the ground truth used in Yueh et al. (1992), where the RMS height is around 1.5 cm and the correlation length is about 13 cm. The ground truth of Yueh et al. (1992) seems to agree well with another experiment study on characterization of agricultural soil roughness for radar remote sensing (Davidson et al., 2000; De Roo et al., 2001). This suggests that the

backscatter from the rough surface might be much stronger than that of Chiu and Sarabandi (2000) if ground truth comparable to that of Yueh et al. (1992), Davidson et al. (2000), and De Roo et al. (2001) were to be used.

In Du et al. (2008) a scattering model for a soybean canopy was proposed which includes the coherent effect due to the soybean structure and takes advantage of the advanced scattering models for rough surface. Some other issues were also taken care of, such as including curvature effect in studying the ground bounce scattering mechanisms and using array theory with perturbation for characterizing the interplant structure to account for the prevailing agriculture practice of soybean.

Electromagnetic wave scattering from cylinders

Determining the electromagnetic properties of those key constituents such as branches and trunks requires knowledge of the scattering properties of dielectric cylinders (Wang et al., 2005; Henin et al., 2007; Ahmed and Naqvi, 2008). In addition, in studying scattering and absorption of electromagnetic waves from ice needles in clouds, the dielectric cylinder are also used to model those needles (Yeh et al., 1982). Thus, finding an effective method to calculate the electromagnetic scattering by dielectric finite cylinders motivated many authors. Because an exact analytical solution for the scattering from finite cylinders does not exist, several approximations have been proposed (Schiffer and Thielheim, 1979; Karam and Fung, 1988; Stiles and Sarabandi, 1996). Among them is the generalized Rayleigh-Gans (GRG) approximation, which was widely applied in the studies of the vegetation samples (Karam and Fung, 1988). It approximates the induced current in a finite cylinder by assuming infinite length. Therefore, this method is valid for a needle-shaped scatterer with radius much smaller than the wavelength. Thereafter, Stiles and Sarabandi (1996) proposed a more general solution for long and thin dielectric cylinders of arbitrary cross section, but still limited to small cross sections. Nevertheless, it should be noted that the solutions of such approximate methods in general fail to satisfy the reciprocity theorem.

In a more general setting, a semi-analytical method named T-matrix approach, originally introduced by Waterman (Waterman, 1956) and is based on the extended boundary condition method (EBCM), is one of the most powerful and widely used tools for rigorously computing volume electromagnetic scattering based on Maxwell's equations and has been applied to particles of various shapes, such as spheroids, finite cylinders, Chebyshev particles, cubes, and clusters of spheres (Mishchenko and Travis, 1994; Roussel et al., 1996; Wielaard et al., 1997). In applying extended boundary condition to calculate the T-matrix that relates the exciting field and scattered field, the exciting field is assumed to be inside the inscribing sphere and the scattered field outside the circumscribing sphere, respectively. However, for particles with extreme geometries

represented by very large aspect ratios, regular EBCM is reported to suffer from convergence problems (Barber, 1954). Physically, this ill-conditioning procedure stems from the fact that, since the exciting field is assumed to be inside the inscribing sphere, for cases of extreme geometries, the exciting fields will not be accurate representative of surface currents. Nor will the scattered fields.

One approach for overcoming the problem of numerical instability in computing the T-matrix for spheroids with large aspect ratio is the so-called iterative extended boundary condition method (IEBCM) (Iskander et al., 1983). The main feature of this technique is to represent the internal field by several subregion spherical function expansions centered along the major axis of the prolate spheroid. The contiguous subregional expansions are linked to each other by being matched in the overlapping zones. The set of unknown expanded coefficients of internal field can be determined by using the point-matching method (PMM). It has been reported that in some spheroidal cases, the use of IEBCM instead of the regular EBCM allows to more than quadruple the maximum convergent size parameter. However, because the first step in this procedure is to approximate the highly lossy dielectric object with a perfectly conducting object of the same shape for its initial solution, it is restricted by the conductivities of the dielectric particles and the maximum convergent size parameter of EBCM for such perfectly conducting object. Moreover, as pointed in (Kahnert, 2003), PMM is less flexible in terms of applications to different particle shapes due to the fact that, the more the particle's geometry departs from that of a sphere, the more unsuitable the expansions of the fields in spherical vector wave functions. Thus, elongated particles require the use of specially adapted PMM implementations with longer computation time and higher computer-code complexity. Another similar technique using PMM to solve scattering from particles enclosed by smooth surfaces is the general multipole technique (GMT), which represents electromagnetic field vectors by multiple spherical expansions about several expansion origins which are located at appropriate positions in the interior region (Al-Rizzo and Tranquilla, 1995). The GMT has been successfully used for particles with smooth surfaces, such as hemispherically or spherically capped cylinders, yet there are issues when it is used in the scattering computations of finite cylinders with flat ends reported. Recently, null field method with discrete sources (NF-DS) is proposed to deal with the instability of conventional EBCM (Doicu and Wriedt, 1999; Eremina et al., 2004; Wriedt et al., 2008). Its numerical stability is achieved at the expense of considerable increase in computer complexity, and the resolution of this method can be affected by the localization of the sources.

A new iterative technique was proposed for electromagnetic scattering by finite dielectric cylinders with large aspect ratio (Yan et al., 2008). With the understanding that for such cylinders a direct application of

the EBCM often leads to numerical instability, the procedure starts by dividing the cylinder into several identical subcylinder to reduce the aspect ratio for each part to which the EBCM can be applied. One of the technical issues that the iterative approach confronted is this: Since any two neighboring subcylinders are touching via the division interface, the conventional multiscatterer equation method is not directly applicable because it requires that the circumscribing spheres of the subcylinder exclude each other (Tsang et al., 1985). Rather, boundary conditions at the division interface need to be satisfied and carefully incorporated into the EBCM formalism. The subtlety lies in the fact that boundary conditions at the division interfaces are point-wise while the EBCM is in an integral form. For such concern, some intermediate variables that have specific meanings are introduced, where the boundary conditions are incorporated. Moreover, since these variables are expressed in terms of surface integrals, the drawbacks of PPM inherent in IEBCM or GMT are avoided. The intercoupling relations of multipole expansions for subcylinder are constructed with the help of translational addition theorems and can be solved iteratively. The impact of translational addition theorem on the convergence property of the resulting linear system is also carefully treated in the iterative procedure.

Summary

The Maxwell equations lay the foundation of all classical electromagnetic phenomena. They describe how time-varying electric fields give rise to magnetic fields and vice versa. At boundary of two different media the permittivity, permeability, and conductivity can change sharply. Boundary conditions are discontinuity equations to specify corresponding discontinuity in the field vectors. Scalar and vector potentials are useful auxiliary functions in analysis of an electromagnetic field, under Lorenz gauge condition the decoupled equations of the potentials identically satisfy the Maxwell equations. Green's function is an important tool in obtaining the solution for general source distributions. Poynting's theorem is a law of conservation of energy for the electromagnetic field. Plane waves are the simplest and fundamental electromagnetic waves. In remote sensing applications, electromagnetic wave scattering from randomly rough surfaces, from vegetation canopies, and from cylinders are important and ongoing research topics.

Synonyms

Emerging societal benefits

Definition

Application. An application of remote sensing is a practical use of information obtained with the technique of remote sensing. Applications are distinct from scientific investigations or engineering development in that their purpose is to consume and apply remote sensing information rather than create and understand it.

Emerging. An emerging application is one in which a new means for using remote sensing information is developed to address a new problem, exploit a new opportunity, or perform an existing function in a new way.

Introduction

Beyond its tremendous value for understanding the Earth, remote sensing also provides a myriad of more practical benefits to society (Group on Earth Observations, 2005). The National Research Council, in its landmark 2007 Decadal Survey of Earth Science and Applications (National Research Council, 2007), underscored the importance of this balance by noting that “attention to securing practical benefits for humankind plays an equal role with the quest to acquire new knowledge about the Earth system.” This balance is critical; remote sensing’s practical benefits (commonly referred to as *applications*) often arise as a direct result of the cutting-edge knowledge developed by pursuing remote sensing science.

Society’s growing need for remote sensing applications is clear. The transformation from an industrial economy to an information economy is driven by knowledge; remote sensing applications are a key element of this progress. Solutions for many of today’s critical societal needs, from health to natural disasters to the environment, require sophisticated knowledge about the Earth and its workings. The defining question addressed in this entry is simple: How will remote sensing be used by society – beyond the underlying science – in coming decades?

Classes of applications

To anticipate remote sensing applications that are likely to emerge, it is first helpful to understand today’s applications, how they are used, and what motivates their development. While these applications can be categorized in a number of ways, an effective approach is to separate them by public sector, consumer, and business uses. The boundaries between these categories may be fuzzy, but the distinctions between them are meaningful.

The *public* sector, with its obligation for ensuring the security and prosperity of the population it serves, applies

remote sensing for a wide variety of purposes. The most prevalent use of remote sensing has long been surveillance for intelligence and military use. In the civilian arena, categories of applications are often described as “societal benefits.” The most definitive list of such benefits comes from the Group on Earth Observations (GEO) and includes (a) disasters, (b) health, (c) energy, (d) climate, (e) agriculture, (f) ecosystems, (g) biodiversity, (h) water, and (i) weather. Various international and national governmental bodies (such as the United Nations Environment Programme (UNEP) and Europe’s Global Monitoring for Environment and Security (GMES)) exist to develop and use applications, but much of the applications work occurs at the regional and local governmental levels. Typical applications functions within governmental bodies include decision systems, assessments, planning, and monitoring. As with most governmental activities, new public sector applications tend to emerge through deliberate planning processes.

The *consumer* market is a growing user of remotely sensed information. The rapid adoption of consumer mapping in the last several years, both online and through personal navigation devices, provides the most tangible evidence. Remote sensing has become increasingly embedded in consumer applications, often in ways that are not obvious. Remote sensing information is now used in consumer video games, as a framework for sharing images and videos, to plan both local trips and vacation travel, to communicate news events, for exploring real estate, and much more. New applications are largely motivated by the growth of existing markets or the anticipation of new markets. In many cases, remote sensing information creates value not by being an end-use product or service itself but through enabling the purchase of other products and services (online store-locator mapping being one example).

The *business* sector employs remote sensing in two basic ways: as elements of the products and services they sell and to improve the efficiency of their business operations. Imagery from both satellites and aircraft is used to help manage operations – through functions such as geographic information systems (GIS), business intelligence, fleet management, and situational monitoring.

Context of historic trends

For much of its early history, remote sensing was dominated by the surveillance applications of the intelligence community, with an emphasis on high-resolution imaging. This information was often tightly controlled. Starting in the 1970s, the use of remote sensing for regional and global civilian applications expanded as datasets such as those supplied by Landsat and geostationary weather satellites became widely available. In the 1990s, the paradigm of Earth system science led to more sophisticated applications that began to integrate remote sensing observations from multiple sources. Finally, the rapid spread of personal computing and Internet access during the early

2000s made it far easier for businesses and consumers to access remote sensing information, triggering a wave of innovative applications. Overlaid on these four historic periods were the many evolving demands for applications, from the exploding needs of emerging economies to the globalization of commerce.

These historic trends provide a context for the ways in which applications of remote sensing have evolved. Over the last half century, applications have transformed from being a specialists' tool to a public utility, from the activities of individuals to the work of groups, from government-driven to business- and consumer-oriented, from slowly produced to rapidly distributed, from single-discipline to multidisciplinary, and from text-based to highly visual.

Current and future trends

The applications that will arise over the next several decades can be expected to reflect the classic balance between trends in user pull and technology push.

From the perspective of user pull, three applications areas are likely to be particularly important. Environmental security encompasses a number of disciplines for which remote sensing is quite useful. Environmental treaties have proliferated over the last several decades; remote sensing is critical to compliance monitoring and assessment. The growing importance of international climate agreements will only accelerate this need. Many nations are also beginning to recognize the strategic importance of the environment to their national security and economic prosperity, from preservation of water resources to understanding global demographic shifts. One important trend has been to aggregate environmental applications as a set of "ecosystem services" (Millennium Ecosystem Assessment, 2005) – a new approach that leverages market forces by managing Earth's resources as assets (similar to how businesses manage their physical assets). A second important applications area is *business efficiency*. As global markets mature, businesses seek to maintain financial margins by improving operational efficiency. Information technology, and geospatial information in particular, provides particularly high leverage for these businesses. Remote sensing applications can improve asset management, operational responsiveness, energy efficiency, and more. Third, *consumer products and services* using remote sensing are likely to grow dramatically and could substantially alter the nature of remote sensing applications. Typical consumer uses range from navigation to online commerce to gaming. The consumer market is by far the largest component of the global economy, so growth in consumer uses of remote sensing can inject substantial resources into applications development. Many important societal trends cut across all three of these applications areas, from the increasing focus on health issues to the importance of energy.

From the perspective of technology push, a wide variety of trends will shape the future. Ongoing improvements

to passive sensors, increased availability of active sensors (radars and LIDARs), and advances in sensor platforms will drive enhanced spatial and temporal resolution. Closely associated are the processing techniques used to transform data into knowledge. These range from algorithms of critical global importance, such as those designed to extract climate information from infrared radiance measurements, to seemingly trivial but high economic-value consumer image-processing algorithms such as red-eye removal. Essential to data processing advances are the ability to integrate (or fuse) data from multiple sources and automation of complex algorithms to facilitate low-cost operation across large datasets. Progress in many of these areas is also greatly enhanced by the development and use of standards, allowing easier interoperability. An often under-recognized area of sensor improvement is human-scale sensors, from professional devices for uses such as surveying to consumer sensors such as digital cameras.

Among the most important trends in supporting technology is the advent of publicly accessible satellite-based global positioning information from the US Global Positioning System (GPS), European Galileo, and Russian GLONASS satellite systems. Computing capability is also critical: Processing power continues to be characterized by Moore's Law, and similar progress metrics apply to information storage capacity and communications bandwidth. Of particular importance, the recent advances in computing and Internet access have seeded a demand for information that extends to the individual consumer. As with the development of television, this "democratization" of information is increasingly funded by advertising, ensuring that the ability to meet demand is not limited by access cost. Information access is also increasingly peer-to-peer rather than from centralized sources, with social networking and information-sharing software being the primary current drivers. The global trend toward universal availability of mobile communications devices, even within the developing world, greatly facilitates this progress. Finally, widespread access to digital photography (in part through inclusion of cameras on mobile telephones) is making people more familiar with the uses of imagery and creating a class of information that can augment and enrich the traditional government-owned sources of remote sensing information.

The rate at which new remote sensing applications emerge based on these trends will also be modulated by larger societal "megatrends." Crisis situations, from military conflict to long-term natural disasters, tend to be strong motivators for rapid advances in remote sensing. The global response to climate change and the international competition for energy may be such drivers; others that are more difficult to anticipate are likely to arise as well. Major changes or opportunities in global economic markets are a second important large trend. The market transformation created by the Internet and the shift of economic growth toward developing nations are important examples.

Characteristics of emerging applications

Emerging remote sensing applications are typically characterized by one or more of the following general attributes:

- *New uses for existing remote sensing capabilities.* Examples include migration of established remote sensing techniques to new markets and new public sector uses arising from newly created programs or agencies.
- *New sensors or techniques which enable applications that were previously technologically, economically, or functionally prohibitive.* In many cases, the applications needs of governments and businesses are well known, but they are difficult or too expensive to address until technology advances make them feasible.
- *New ways of analyzing, processing, or combining remote sensing information.* Useful applications often require extensive algorithmic processing of raw data. Progress is enabled by algorithm development and advances in computing power.
- *New science that enables new uses.* Scientific investigations using remote sensing routinely expand our knowledge of the Earth. This knowledge is used to enhance existing applications and to motivate development of entirely new applications.
- *Technological advances in related areas.* Many new applications emerge as a result of collateral technology advances in computing, communications, and satellite navigation.

These general attributes provide the framework for specific characteristics of emerging applications that can be anticipated over the coming decade and longer:

- *Real-time applications.* The need for remote sensing applications is often time critical, yet access to sensor information and the required processing can take hours or days. Satellite providers have recognized this and are emphasizing reduced revisit times for low-Earth-orbit constellations, radar sensors that can image at night, geostationary platforms to provide persistent imaging, and rapid deployment of aerial platforms (including drones). Advances in automated processing have also been critical to achieving rapid information dissemination.
- *Multidisciplinary integration.* Simple applications tend to focus on a specific need or single information source. The maturing of remote sensing has enabled development of applications that begin to connect multiple information sources. This can involve data from multiple scientific disciplines (e.g., weather and oceans) as well as diverse types of information ranging from science and business.
- *Shared and multiuser applications.* Until recently, most web-based software followed the server–client architecture, in which a centralized server publishes information to multiple users. Increasingly, web-based software employs a peer-to-peer architecture

(commonly referred to as Web 2.0 and social networking) that facilitates direct sharing of information between individual users. Similarly, applications have begun to support multiple simultaneous users, enabling shared viewing of dynamic content and collaborative editing of information.

- *Transition from text to visualization.* Visualization is a highly effective means for communicating large amounts of information, particularly when spatial information is involved. Extensive visualization within applications requires systems with large bandwidth and considerable data storage, capabilities that have become widely available within the last few years.
- *Integration across spatial/temporal scales.* Applications have historically been constrained in spatial and temporal scale: limited to a global, regional, or local use and focused on either long-term or short-term. Applications that support linkages between scales are rapidly emerging. A prominent example is medium-range [weather forecasting](#) that integrates multidecadal global climatology, regional/seasonal patterns such as El Niño, and localized hourly weather forecasting.
- *Improved data archive and access.* As information volumes have grown, the ability to archive, find, and rapidly access information has become a significant challenge. Considerable resources are being applied to this problem through web-based search, including the areas of metadata, data tagging, indexing, and vertical search. With increasing consumer use, the business model for accessing remote sensing information has evolved; instead of end-users paying for access to the basic data, revenue increasingly comes from use of the applications that consume this data, including “free” applications monetized through advertising revenue.
- *Rapid, widespread communications.* Effective applications quite often require the rapid and widespread dissemination of information, decisions, and alerts. The ongoing revolution in mobile communications, both networks and handsets, has opened many new opportunities for remote sensing applications. Coupled with the Internet, mobile communications enable broad global information sharing and ready access at the point of use.
- *Merging of real and hypothetical information.* The transition from analog to digital information has made possible extensive processing and reprocessing of information. Within this context, it has become easy to combine or merge real and hypothetical data, and this has proven valuable for remote sensing applications. Simple examples are the 3D visual representation of a city modified to include a hypothetical development project and the visualization of hypothetical ecosystem changes brought on by climate change.

Anticipated applications

Based on these trends and characteristics, it is possible to anticipate several important classes of applications for the next decade and beyond. *Environmental services*, both

for government and business use, will almost certainly lead the way. These will encompass enhancements to existing applications, such as weather forecasting and resource management, as well as new applications to support emerging needs in the areas of climate, energy, air quality, and health. Society's increasing sensitivity to human and property losses from natural disasters will motivate improved applications addressing *disaster prevention and response*, with emphasis on communicating centralized information and decisions to the general population. The private sector will increasingly integrate remote sensing and other geospatial information into their operations to improve *business competitiveness and efficiency*. Both businesses and consumers will benefit from the growing availability of *location-based services* and augmented reality, allowing them to get information, make decisions, and perform functions specifically tailored to where they are or where they are going. Associated with this will be significant advances in the capabilities of *personalized mapping*, the ultimate tool for getting remote sensing out to the individual, including both Internet and mobile uses. Finally, *gaming and entertainment* cannot be underestimated due to the considerable financial resources available within this market; innovative uses of remotely sensed information will be developed to enhance the realism of applications in these areas.

It is also possible to anticipate some of the more innovative applications that may emerge in coming decades. High on this list are applications that involve *community-based mapping and remote sensing*. The ability of government and businesses to monitor the Earth at all space and time scales is currently highly constrained. Community-based data gathering (with sensors such as mobile phone cameras), and community-based applications, will be increasingly important. Various technological advances, from the proliferation of mobile phones to the spread of social networking software, make this possible. Linkages between these community-based networks and more formal government/business networks will leverage the capabilities of each. As the world becomes increasingly monitored across all space and time scales, this knowledge will further our ability to create replicas of the real world – 3D *virtual worlds* in which many of the real world's functions can be mirrored. These worlds – built and updated with remote sensing information – provide a virtual context in which applications can be visualized and applied without the constraints encountered in the real world. Perhaps most exciting, they create a platform for “what if” applications, allowing us to implement functionality (“experience a tsunami”) and perform actions (“assess the societal consequences of a global crop blight”) that cannot be accomplished within the real world for safety, ethics, or other considerations.

Summary

Applications of remote sensing have proven, over the last several decades, to have tremendous benefit to

society – increasing our prosperity and making us more secure. The need for such applications is only accelerating as we transform from an industrial society to one that is information-driven. Advances across all areas of remote sensing, as well as the enabling computing and information technologies, ensure that emerging applications of remote sensing will be increasingly important to society's progress.

Active sensing; Data Management; Instrument; Passive sensing; Technology trends

Definition

Technologies to enable measuring new science requirements.

Emerging technologies

The objective of the *emerging* technology area is to develop highly capable instruments that are a key element in contributing to an ability to successfully develop and operate high-performance future remote sensing missions. The current state of the art remote sensing sciences tend to demand higher special and spectral resolution from next generation remote sensing capabilities. With a growing emphasis on cost-effective approaches due to high spacecraft and launch vehicle costs, multiband and low mass sensors are of key interests in this area.

There are a number of high payoff technologies within this area that include active remote sensing, massive data processing techniques, and technology push. The primary technology challenges for active remote sensing is

development of systems in ever-broadening envelopes of transmission; large aperture, light-weight, high-efficiency, and high-power transmitters; and reliable systems. These technologies will enable [RADAR](#) and [LIDAR](#) for a consistent coverage of the globe for CO₂, biomass, cryosphere, water cycle, and earthquake (Richard et al., 2007).

There is a robust and mature capability that is in place for Earth science enterprise to understand surface, ocean, and atmospheric characterizations of Earth. There have been many high resolution instruments to measure various parameters to study Earth such as [RADAR](#), [LIDAR](#), hyperspectral imager, and spectrometer instruments. With use of distributed data architecture, Earth science enterprise distributes data based on middleware architecture and provides a framework for data mining, modeling, simulation, and visualization capability. With significant increase in data volumes, traditional methodology for data processing will not be able to meet challenges of high-throughput modeling and data extraction. These developments should be incorporated to provide a uniform interface to the operational team. Handling large volume of data and information generation to decision support should take advantage of advancement from GIS and industry de facto standards.

In addition to the high-capability technology areas that are discussed, it is important to note the technologies that promise the future. These are the innovative technologies that have the potential to enable critical new science or exploration capabilities. These are promising because they do one or more of the following: stretch the state of the art in some respect, have the potential for high performance, provide a novel operational concept, and attempt to perform a measurement in way never before envisioned. For technology push areas, the technologies required for these instruments focus primarily on detector technology, whether in the detector sensitivity, size of detector arrays, or detection stability and calibration. For some applications, large apertures are also a challenge. In the areas of in situ sensing, challenges associated with in situ sensors focus on development of sensor webs that produce science-lab quality measurements in a field instrument. Furthermore, high-capability instruments tend to produce a lot of data volume and would require high downlink capability; optical communication will play an important role in the future.

Summary

Future science requirement demands higher resolution and temporal coverage. Active sensing techniques and large focal plane array detection will enable those objectives along with communication and information technology infrastructure.

EMERGING TECHNOLOGIES, FREE-SPACE OPTICAL COMMUNICATIONS

Hamid Hemmati

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA, USA

Introduction

Future pursuit of the vision for robotic and human space exploration would utilize instruments with ever-increasing capability and require orders of magnitude increase in data return rates from planetary distances. Without resorting to high-power transmitters with hundreds of watts and antenna diameters on the order of 5 m, deep-space science and exploration will rapidly encounter a bandwidth ceiling with radio frequencies of S, X, and Ka bands. In addition, communicating at a given data rate with an outer planet such as Neptune or Pluto is 1,000 times more difficult (when considering link margin degradation) than communicating at nominal Mars distance. Similarly, a link from Mars is approximately 10 billion times more challenging than communicating from geosynchronous orbit (GEO) to the ground (Hemmati, 2006). On space platforms, mass and electrical power are expensive commodities, and thermal gradients and ionizing radiation pose challenges as well (Hemmati, 2009).

Laser communications (lasercom or optical communications) through free-space, utilizing a narrow laser beam transmitted from planetary distances, hold great promise for delivering the increased data rates while imposing reasonable mass and power burdens on a host spacecraft. This technology has the potential to enable deep-space communication between Earth and planets at the farthest reaches of our solar system and beyond. In the coming decade, with comparable mass and power of a radio-frequency communication system (including optics one tenth the diameter of the flight antenna aperture), lasercom systems are expected to deliver at least an order of magnitude higher

data rate than conventional radio-frequency systems. Lasercom could offer these benefits with no additional attitude-control burden on the spacecraft and any spectrum bandwidth allocation or restrictive frequency regulations.

The high-capacity communications offered by lasercom could enable scientists to communicate information from other planets using, for example, streaming HDTV video, synthetic aperture radar, multi- and hyperspectral imagers, precision navigation, and multichannel telecommunications. Additional possibilities are multifunctionality with space-based optical navigations, laser remote sensing, imaging, and altimetry (Hemmati and Lesh, 1998).

Recent highly successful in-space validations of lasercom technology (e.g., GOLD, GeoLITE, SILEX, and TerraSAR-X) have led to the development of operational systems (Wilson et al., 1997; Caplan, 2007; Tolker et al., 2002; Smutny et al., 2009). Although lasercom has been fairly well proven in the Earth's orbit, it will need to undergo a number of successful deep-space demonstrations – with an order of magnitude higher data rate and at a lower cost per bit than conventional systems – before it can be operationally implemented in space. To date, there have been no laser telecommunications with a planetary spacecraft, although there have been demonstrations of aiming a ground-based laser at spacecraft into deep space, and vice versa (Wilson et al., 1993; Smith et al., 2006).

An introduction to significant system design and system engineering aspects of the flight and ground portion of a planetary laser communications will follow.

System design and engineering

Telecommunication at planetary distances involves link ranges that can range up to billions of kilometers. Due to the $1/r^2$ dependence for the space loss factor, a system engineer faces the challenge of designing a system that can compensate for an additional loss of 60 to greater than 100 dB over that of a near-earth satellite-to-ground link. A clear improvement area is to increase the aperture diameter at both ends of the link (Hemmati et al., 2007). However, an increased flight transceiver aperture exasperates the laser beam pointing challenge, since efficient implementation necessitates beam pointing to the order of one tenth of the telescope's beamwidth. Moreover, larger ground apertures collect larger amounts of background light, and even the highest quality telescopes are constrained by atmospheric turbulence-induced spreading of the signal (blur circle) at the telescope's focal plane. As discussed below, before a system can be designed, the link requirements and parameters have to be considered in its entirety.

Constraints and desired characteristics of an optical link

Although optical communication systems offer many potential advantages in deep data return capability, the current implementation also has a number of limitations that can affect the link availability and overall data return strategy. These constraints include limited weather-related

availability from a given ground station and limited solar conjunction availability arising from Sun platform geometry. Also, until the spacecraft/mission design can provide sufficient confidence in autonomous systems, radio-frequency (RF) link coverage (albeit with reduced capability) will likely augment the optical link during the attitude-constrained mission phases and critical maneuver.

Desired characteristics of an optical link include (Hemmati, 2006):

- Support high data rates that are competitive to RF implementation
- Support bidirectional links and spacecraft navigation
- Provide high reliability
- Low mass, power consumption, and volume
- Radiation tolerant
- Not to place demands on the host platform
- Provide extended mission coverage
- Function at small Sun angles

Major design driving issues include:

- Stabilization and pointing of the narrow laser beam transmitted from the remote platform
- Minimization of scattered light, thermally induced telescope deformations, and avoiding telescope damage – considering that transceivers at each end of a link must typically look near the Sun in order not to avoid operational downtime
- Rejection of as much of the collected background light as is feasible (e.g., via optical filtering) prior to data detection

End-to-end link block diagram

A top-level, end-to-end signal flow for an optical communications signal flow is depicted in Figure 1. Mismatch among various blocks or performance degradation in any subsystem block, for example, due to device aging or radiation damage, will result in reduced efficiency of data transmission. The host platform random vibrations, the space platform/transceiver interface, and the space environment (radiation and vacuum) can all influence the flight transceiver's behavior.

Communications link design

The link design control table (DCT) is a listing of link influencing design parameters, such as aperture size, output power, and other requirements placed on the transmit and receive transceivers, and the resulting estimated system at a specific point in time during the mission (Hemmati, 2006). DCT analysis, with the primary purpose of estimating the required signal power to be delivered to the opposite terminal and available margin to maintain the desired link performance for a given worst-case condition, is a critical consideration in the design of a laser communications system.

Factors driving the link analysis are (1) fixed requirements/specifications (e.g., link distance, data rate, and bit error rate) provided by the user, (2) those fixed by laws of physics (i.e., space loss), (3) variables of the hardware

Emerging Technologies, Free-Space Optical Communications, Figure 1 Telecommunications signal flowing from a spacecraft probe to Earth.

design (e.g., aperture sizes and laser powers at opposite ends of the link), and (4) variable hardware qualities driven by implementation approach (e.g., pointing losses and optical losses). By adding the gain factors together (e.g., laser power, photodetector sensitivity, and aperture's area – in units of dBm or dB) and subtracting from the loss factors (e.g., the space loss, mispointing, and imperfection of optics), we are left with the link margin that needs to be positive in order to establish a link.

The mean received signal power at the receiver is related to the transmit power and various link losses, and the transmit and receive antenna gains can be estimated from the following equation:

$$P_R = P_T \eta_T G_T L_{TP} L_{atm} L_s G_R \eta_R$$

Where

P_R	Signal power incident on the data detector
P_T	Output power of the laser transmitter
η_T	Transmit optics efficiency, accounting for relay optics transmission, wave front quality errors, and beam truncation
G_T	On-axis transmitter gain
L_{TP}	Transmitter pointing loss
L_s	Space loss
L_{atm}	Atmospheric loss comprised of attenuation and turbulence (beam spreading beam jitter losses)
G_R	Receiver gain
η_R	Receiving efficiency accounting for optical transmission and losses associated with mispointing and detector overfilling or truncation (Hemmati, 2006)

Technologies for data rate generation and detection

In this section, trades on data modulation and reception techniques, coding, laser transmitters, single-photon detectors, decoding, demodulation, and data-receive electronics are discussed.

What detection scheme we use is intertwined with what data transmission format we employ, and vice versa. Both direct detection and coherent heterodyne reception are options for data reception. A direct-detection receiver detects the intensity of the received signal and (without background interference) can achieve performance exceeding that of heterodyne detection. Implementation of narrow field-of-view optical receivers and narrow band-pass filters in the receiver chain becomes essential to mitigate the background noise and improve receiver sensitivity. Coherent (heterodyne) receivers first interfere with the downlink optical signal via a local oscillator (laser) prior to photodetecting the combined signal. The signal beam mixing process is mode-selective spatially, and only the signal energy that is mode matched to the local oscillator beam is detected. Therefore, the coherent detection scheme is largely immune to background light noise. However, the coherent receiving process is significantly more complex, particularly for a downlink signal that has traversed the turbulent atmosphere.

Considering the photon-starved regime of operations at ranges typical of planetary distances, our overall goal is for the most efficient detection (measured by the

Emerging Technologies, Free-Space Optical Communications, Figure 2 Example of a coded transmit optical channel, modulated in PPM format.

unit of bits/photon). Coherent receivers utilizing either homodyne techniques or heterodyne techniques with coherent IF electronics have achieved as much as -3 dB bits/photon (for homodyne-detected) signals (Borson, 2007). The receiver sensitivity for (typically) photon-starved regime planetary communications links is of critical importance. The required receiver sensitivity is on the order of a few photons/bit for expected telemetry downlink communications rates, ranging from 10 to 100 s of megabits/s.

Phase fluctuations (arrival angle variations) constitute the primary influence of turbulent atmosphere on a direct-detection receiver since, by utilizing large (multimeter) diameter ground-based telescopes, the scintillation effect is averaged out to a great extent. In direct detection, the atmospheric turbulence limits the phase coherence across the telescope's optical aperture to a distance of r_0 , known as the Fried's atmospheric coherent length (Andrews and Phillips, 2005). The value of r_0 is highly variable, depending on the receiver site and the time of day, and can vary from a few centimeters (daytime – poor seeing conditions) to tens of centimeters (nighttime – excellent seeing conditions). For distances up to r_0 , arrival angle/phase remains mostly correlated. Once the daytime adaptive optics technology is sufficiently advanced, a substantial portion of the turbulence effect on the lasercom signal can be mitigated.

Currently, coherent detection approaches require single-spatial-mode reception. However, propagation of the laser beam through the turbulent atmosphere results in distorted (non-flat) wave fronts, leading to an enlarged blurred circle (multimode beam) at the telescope's focal plane. In the absence of an often elaborate adaptive optics system for a large ground-based telescope, the multimode beam is unsuitable for both coherent mixing with local oscillators and for coupling to single-mode fibers. Implementation of adaptive optics during daytime and meeting the unique requirements imposed by lasercom on adaptive optics (for generation of very high Strehl ratios – approaching 1.0) require additional technology development (Wilson et al., 2003). In the absence of an atmosphere (e.g., cross-links between assets above the atmosphere), coherent detection would provide a highly competitive performance.

For a turbulence-constrained system, the simplest detector is one that provides what is known as “direct detection.” The most efficient detector of this kind is sensitive to single photons and counts individual photons with high-detection efficiency and extremely low noise (discussed in further detail later) (Farr, 2009). For this detection scheme, the

requirement for spatial coherence is relaxed to levels sufficient for focusing a received beam onto the active area of the photodetector, located at the focal point of the optical aperture, and collecting the received photons.

Modulation and coding

Figure 2 shows an example of signal flow through a coded free-space optical channel. Coding gains exceeding 5 dB can now be expected from the advanced high-efficiency codes, approaching to a fraction of a dB of the Shannon capacity limit (Hamkins and Moision, 2004). The resulting link efficiency gains have the direct effect of relaxing requirements on the transmitted laser power and telescope's aperture diameter, resulting in an overall simplification of the flight transceiver.

One may model a direct-detection free-space optical link as a Poisson point process, with system limitations on bandwidth, average power, and peak power (Moision et al., 2006). Under these constraints, a negligible capacity loss is encountered when confining the modulation to a binary, slotted format (Moision, 1999). The capacity of an optical channel, which represents the highest data rate that the channel can consistently support, depends on multiple factors including the modulation format, the medium through which the beam traverses, the optical preamplifier (if any), and the photodetector. A channel error-correction code (ECC) may be found with negligible output probability of error, when data rate is less than a given channel's capacity. However, the probability of error is enhanced when the data rate exceeds the channel capacity (Wyner, 1988).

Most efficient optical links result when the received signal's peak-to-average power ratio is high (Hamkins and Moision, 2004; Lipes, 1980). M-ary pulse-position modulation (PPM) is a modulation scheme that can create such a condition – resulting in near-capacity performance and negligible loss relative to alternatives. In the PPM format, $\log_2 M$ bits choose the location of a single-pulsed slot in an M-slot frame (Hamkins, 2008). Error-correction codes based on *serially concatenated codes* have been designed for the PPM channel, where the constituent codes are:

- Convolutional code serially concatenated with PPM (and preceded by a bit accumulator)
- Low-density parity-check (LDPC) code concatenated with PPM (Tan et al., 2008)

These codes – when used in conjunction with photon-counting detectors – achieve efficiencies better than 1 dB photons/bit. Implementation of PPM does result in

Emerging Technologies, Free-Space Optical Communications, Figure 3 Efficiency of state-of-the-art optical codes compared with channel capacity.

finite losses (due to modulator constraints) and more importantly necessitates high (kW level)-peak-power lasers.

Figure 3 shows the power efficiencies available at various data rates, using current technology of modulation, coding, and reception. On-off keying (OOK) modulation in conjunction with low-noise optically preamplified receivers is a common approach for fiber-optic telecommunications at rates exceeding 40 Gb/s. Utilizing the best available decoder chips, in conjunction with Shannon capacity-achieving codes (e.g., turbo codes) and soft decisions, efficiencies on the order of 6 dB photons per bit (at 10^{-9} BER) have been achieved (Kiasaleh, 1998).

Figure 4 shows the efficiency of PPM at differing alphabet size, M . This figure illustrates how one may trade bandwidth for efficiency by using higher and higher M , and how a noisy environment significantly degrades the performance efficiency of a photon-counted PPM-modulated signal (every 3 dB of extra noise requires about 1 dB of extra signal) (Dolinar et al., 2000). The difference between a noiseless and just one noise count/slot can be as much as 10 dB of efficiency, diminishing the significant advantages provided by the photon-counting technique (Moision and Hamkins, 2003).

Laser transmitter

Implementation of high-order PPM requires laser transmitters with a high peak-to-average power ratio.

Emerging Technologies, Free-Space Optical Communications, Figure 4 Efficiency of different PPM orders indicating that the recently developed codes for optical detection are within a fraction of 1 dB of capacity limit. PPM capacity on the additive white Gaussian noise (AWGN) channels is compared with other performance curves.

Emerging Technologies, Free-Space Optical Communications, Table 1 Current status of key single-photon-sensitive detectors

Detector	Wavelength (nm)	Detection efficiency	Dark rate (Hz/mm ²)	Notes
Geiger-mode APD	400–850 900–1,600	40 % 55 %	1E6 2E4	High jitter. Reset time with each detection event
Intensified hybrid photodiodes	900–1,600	40 %	1E6	Photocathode degradation
Superconducting	400 to > 1,600	80 %	1E2	3°K temperature operation
Negative avalanche feedback	450–800 900–1,600	35 % 11 %	3E4 5E8	Intolerant of over bias. Low maturity

Master-oscillator power-amplifier (MOPA) sources based on Yb-doped fiber (operating at 1,060 nm) or Er/Yb-doped fiber (operating near 1,550 nm) satisfy this requirement and are compact enough for spacecraft use (Hemmati, 2009). Modulation extinction ratios on the order of 80 dB have been demonstrated with picosecond lasers (Braun et al., 1995). Also, mode-locked fiber lasers with 1 GHz pulse repetition rate and over 60 dB secondary mode suppression have been achieved (Deng et al., 2004).

Utilization of the laser in deep space also necessitates an overall high (input electrical to optical) efficiency of operation. A wall plug oscillator/amplifier efficiency of greater than 30 % is theoretically achievable (Hemmati et al., 2000). Currently, 1,060 nm lasers are proving to be more efficient than their 1,550 nm counter parts (Wysocki et al., 2006; Spellmeyer et al., 2005). MOPAs modulated at hundreds of megahertz with average output powers exceeding 10 W, peak powers approaching 1 kW, and sub-ns pulses are now available (Dupriez et al., 2006). The performance of current fiber amplifiers is limited by self-phase modulation (SPM) and to a lesser extent by stimulated Brillouin scattering (SBS) nonlinear effects when pulse width is <0.1 ns (Charplyvy and Tkach, 1993).

Laser designers also emphasize suppression of undesired background radiation noise, known as amplified spontaneous emission (ASE), which is generated along with the amplified signal (Bromage et al., 2003). ASE's spectrum spans that of the amplifier's gain profile and maintains the same polarization as the amplified signal. This can cause transmit/receive isolation challenges for the transceiver. Winzer et al. show that for near-Earth ranges of communications, the ASE noise levels may rival the background radiation received from the Sun (Winzer et al., 1999).

Uplink laser(s) for transmitting data to spacecraft and/or as a beacon (to assist with the acquisition and tracking of the earth station by the remote transceiver) typically requires orders of magnitude higher power and orders of magnitude lower pulse repetition frequency (Biswas et al., 2005). Unlike the downlink laser, sub-nanosecond pulse widths will not be required for the uplink laser.

Single-photon-sensitive photodetectors

Efficient detectors at each end of the optical communications link reduce the required laser power at the opposite end of the link. Top-level photodetector requirements,

when employing PPM modulation in conjunction with photon-counting receivers, include high single-photon detection efficiency, low output pulse timing jitter, low reset time, large active area simultaneously with high bandwidth, and low dark count rate (Robinson et al., 2005).

The advent of new generations of ultra-low-noise, high-gain, and high-bandwidth single-photon-sensitive detectors (also known as photon counters) has resulted in nearly 8 dB of link margin gain relative to APDs, enabling optical communication links with sensitivities approaching one photon/bit (Farr, 2009; Stern and Farr, 2007). When photon counters are utilized along with near optimal (channel capacity approaching) codes and high peak-to-average power lasers, nearly 20 dB gain may be realized relative to direct-detection systems operating with on-off keying (OOK) modulation (Borson, 2007). Minute levels of detector noise also enable implementation of an array of optical receivers each equipped with a photon counter, followed by electrical signal summation (Quirk and Gin, 2006). Table 1 compares current merits of leading photon counters.

The *reset time*, an imperfection that is characteristic of most photon counters, is the period of time for which the detector is inactive upon each signal or noise detection event (Kerman et al., 2006). Depending on the detector type, the reset time period may span from a few nanoseconds to a few milliseconds. This drawback limits the achievable data rate and the total detectable photon flux (detection event/s).

For detection of very faint signals and to avoid detector shutdown due to dark count events, it is advantageous if the mean time between dark count (noise) signals is shorter than the reset time (Kachelmyer and Borson, 2007). In a photon-starved regime (such as planetary links), daytime background light flux exceeds dark count rate of the detector. The minimum resolvable arrival time for a photodetection event is known as the output pulse *timing jitter* of a given detector (Moision, 2008a). This timing resolution restricts the number of bits accessible from each detection event, setting an upper limit on the achievable data rate (Moision and Farr, 2008).

Receive electronics

Various architectures have been envisioned for data-receive (synchronization, demodulator, decoder) electronics. In one *distributed and scalable* photon-counting

Emerging Technologies, Free-Space Optical Communications, Figure 5 Schematic block diagram of a generic PPM receiver.

decoder architecture, a receiver that independently synchronizes to the received signal follows each detector (Gin et al., 2007). Sets of pulse-position modulation (PPM) slot statistics generated by multiple receivers are combined in each slot accumulator and fed to a decoder for recovering clock and transmitted data bits. Multiple decoders will be required for high (tens of megabytes per second) data rate links. In distributed decoder architecture, each unit that follows the receiver contains a single PPM decoder. A decoder that is unavailable relays the undecided code words onto subsequent decoders. The receivers, slot accumulators, and decoder boards are connected using multi-gigabit serial deserializers. The distributed decoder and slot accumulator boards may share a common hardware platform but differently programmed field-programmable gate arrays. The scalability feature of this architecture has been utilized to develop receiver electronics for planetary-type links utilizing high-order PPM demodulation/decoding and capable of handling hundreds of megabytes per second of data rate throughput (Moision, 2008b). Figure 5 depicts a generic block diagram of a PPM receiver, including synchronization, demodulation, and decoding of the photodetected signal.

Optics for flight transceiver

Figure 6 shows a generic schematic diagram of the flight optomechanical assembly. This subsystem is comprised of three primary channels: laser beam transmit, data receive, and pointing, acquisition, and tracking. The laser transmitter assembly (typically located remotely to simplify thermal management) is connected to the optics assembly via a single-mode fiber. The data-receive channel may include an avalanche photodiode detector (APD) or a single-photon-sensitive detector. Synchronizer, demodulator, decoder, and amplifiers assisting with

clock and data recovery comprise the remaining receiver electronics.

Channeling the uplink signal to the data receiver may be accomplished through free-space or efficient coupling with an optical fiber. Optical amplification of the received signal is also a possibility, as long as the signal level exceeds the amplifier's noise level. The pointing, acquisition, and tracking (PAT) assembly consists of a dichroic mirror to separate the transmit and receive beam, a two-axis fine-pointing mirror whose function is to remove the host platform vibrations, a two-axis point-ahead mirror to compensate for (point ahead or point behind) angle that arises from the cross velocity between the spacecraft and the target (e.g., Earth), and a focal plane array (FPA) consisting of as little as four pixels to hundreds of pixels. The fine-pointing (fast steering) mirror may require an update rate bandwidth of hundreds of hertz to several kilohertz, depending on the nature of the host platform vibration. It is also conceivable for the PAT's pixilated array to also serve as sensor for uplink data detection (Ortiz and Farr, 2009).

An alternative approach involves use of an isolation platform that combines passive and active isolators, as the interface between transceiver and the host platform (Chen et al., 2006). An advantage of this architecture is elimination of the fine-pointing mirror, since the base plate of the transceiver performs that function. Figure 7 illustrates such a configuration schematically.

The requirement for micro-radian level laser beam pointing necessitates optomechanical and thermomechanical integrity under the adverse conditions encountered in space. Maintaining optical isolation between the high-power transmit beam and the faint incoming beam, typically greater than 150 dB, is often a challenge. Even though transmit/receive signal isolation is more of a challenge for optical systems that combine both the transmitter and the (beacon and signal) receive aperture in one assembly, this configuration is preferred due to

Emerging Technologies, Free-Space Optical Communications, Figure 6 Block diagram example for a transceiver's optics assembly.

Emerging Technologies, Free-Space Optical Communications, Figure 7 Schematic of a laser communication transceiver utilizing isolation platform to simplify its architecture.

lower susceptibility for drift between channels (Chen and Lesh, 1994). A solar background, light-rejecting window at the telescope will minimize heat load from sunlight entering the telescope. Stringent requirements on cleanliness of the optics for flight use are an optical system class with cleanliness of 300 or better. This diminishes the scattered light that can find its way to any one of the sensors in the system (Spyak and Wolf, 1992). Redundancy of channels (if required for reliability reasons) may be implemented by polarization coupling for coupling two units and wavelength diversity for coupling additional units. Fiber coupling of all or some of the channels would simplify the optical assembly, while possibly encountering some additional coupling losses.

Pointing, acquisition, and tracking (PAT)

Fine pointing, acquisition, and tracking (PAT) is conceivably the most critical aspect of any lasercom link. This challenge stems from the narrow beamwidth of a communication beam, requiring the communication system to point its laser beam with sub-micro-radian (μrad) accuracy to a target tens to hundreds of millions of kilometers away. A combination of coarse and fine beam pointing is required to accomplish fine PAT. For planetary missions, a dedicated coarse-pointing mechanism is not required. The coarse-pointing (approximately, 0.1°), typically provided by the spacecraft to the planetary radio-frequency communications systems, is adequate for lasercom transceivers to acquire the Earth-based receiver within its acquisition field of view (Hemmati, 2006, 2009). Fine beam pointing and point ahead/behind is accomplished by way of internal mechanism(s) within the optomechanical assembly.

Prior to commencing a laser communications link between two remote transceivers, a number of knowledge-acquisition and handshaking steps need to be accomplished simultaneously:

- Knowing that the remote transceivers are within each other's field of view.
- Identifying each transceiver's position (e.g., attitude and locations). If range (and therefore roundtrip travel time) is short enough, the position knowledge may be communicated between transceivers.
- Utilizing the acquired position knowledge to derive the pointing vector to the remote transceiver.
- Deriving time-varying attitude variations and utilizing coarse-pointing and fine-pointing mechanisms to align the optomechanical assembly with the pointing vector.

Severely degraded link margin and system performance (signal fades at the receiver) will result from inaccurate laser beam pointing. The pointing loss allocation in the link control table is commonly divided into bias and jitter mispoint errors. Jitter represents high-frequency disturbances – normally root-sum squared to achieve an estimate of pointing accuracy – while bias represents the low bandwidth disturbances, normally added linearly.

The 3 sigma total pointing accuracy is calculated by adding $3 \times$ jitter to bias (Hemmati, 2007).

To account for the statistical pointing-induced fades (PIF) and mispoint angles, a pointing loss is typically allocated to the power link margin. For instance, the diffraction-limited angular beamwidth of a 1,000 nm laser traversed through a 30 cm-diameter telescope is approximately $3.3 \mu\text{rad}$. In this example, a 2 dB pointing loss allocation with a 1 % PIF requires a total (3 sigma) pointing accuracy of $2 \mu\text{rad}$. A promising new loss mitigation technique utilizes interleaver codes that spread the PIF over many code words of an error-correction code (Barron and Boroson, 2006).

Effective delivery of the spacecraft-emanated signal to a ground station requires the lasercom transceiver to track the receiving station such that the tracking jitter error is less than approximately 10 % of the transmit beamwidth (roughly $0.33 \mu\text{rad}$ in the above example) (Ortiz and Lee, 2006). For reference, from Mars, Earth angular extend is about $35 \mu\text{rad}$. Therefore, in the above example, the spaceborne laser beam needs to be pointed to approximately 1/18th of the Earth's diameter, a pointing requirement orders of magnitude more precise than required for RF system operating over the same range.

Spacecraft platform's angular microvibrations (with frequencies in the 0.1 Hz to hundreds of hertz range) stemming from scheduled and unscheduled guidance and control events (e.g., thruster firings and momentum dumping) constitute additional complexities for the already challenging sub-micro-radian level pointing requirement. Passive isolators and inertially referenced stabilized platforms can effectively mitigate the high (greater than several hundred hertz)-frequency vibrations (McMickell et al., 2007). A reliable beacon signal (e.g., laser beam, Sun-illuminated Earth or celestial references), in conjunction with a dedicated fine beam pointing control subsystem, is required to reject lower frequencies effectively (Hemmati, 2006, 2009).

The total laser beam pointing error for an optical transceiver is primarily comprised of inaccuracies in boresight calibration, the errors in position determination, and residual tracking errors not compensated for by the pointing subsystem control loop. A residual tracking error results from inadequate compensation of the host platform vibrations by the pointing control loop. The higher the bandwidth of the control loop, the better the platform jitter compensation and therefore the lower the residual laser beam pointing error. Data from inertial navigation subsystem (located in close proximity with the transceiver) can reduce the required image centroiding update rates from several kilohertz to hundreds of hertz or lower (Ortiz et al., 2001).

As indicated earlier, mounting the lasercom transceiver on a disturbance-free platform (DFP) effectively isolates the transceiver from the host platform, circumventing the need for fast-tracking capability (Scozzafava et al., 2007). Such architecture will minimize the amount of

line-of-sight jitter coupled into the optics assembly and allow the beacon signal analyzing focal plane array to be integrated over a much longer period of time, as well as enable the use of faint reference beacons as pointing references. With the ability for long integration times, laser beam pointing becomes considerably less sensitive to scintillation-induced fades of the uplink beacon, thereby relaxing the spacecraft pointing requirements. Moreover, a DFP can also provide coarse and fine-pointing adjustments, eliminating the need for additional high-bandwidth line-of-sight control (e.g., fast-steering mirror) within the system (Sannibale et al., 2009).

Optical channel (atmospherics)

The adverse effects on a laser beam traversing through the atmosphere may be put into two categories: (1) *attenuation effects*, caused by *scattering* and *absorption*, and (2) *refractive index fluctuation effects*, including spatial and temporal *scintillation*, *angle-of-arrival fluctuations*, large-scale *beam steering*, and *beam spreading*. The net effect of atmospheric attenuation and turbulence on communication link is signal fades, beam spreading at the telescope focal plane, wave front tip/tilt, background light due to sky radiance, signal scintillation, and other undesirable phenomena (Andrews and Phillips, 2005).

Attenuation reduces available signal power at the receiver and is a function of weather conditions, zenith angle, and the receiver site. Scattering is highly variable and depends on particle size in the atmosphere. If δ is the particle size and λ is laser's wavelength, different scattering cross sections (σ) can result depending on the relative size of δ and λ . A laser beam propagating through the atmosphere may experience Rayleigh scattering, which occurs when $\delta \ll \lambda$ (gases), Mie scattering when $\delta \sim \lambda$ (aerosols and fog), and geometric scattering when $\delta \gg \lambda$ (Andrews et al., 2001).

Scintillation is caused by refractive index variations in the atmosphere and results from spatial and temporal variations in light intensity caused by small-scale atmospheric turbulence. This effect creates multipath summation of signals at the receiver, resulting in phase differences for each beam with the net effect of variable arrival angles (Hemmati, 2006, 2009). Strong scintillation is difficult to characterize well, affects bit-error-rate performance, its influence increases with communications distance, and is more pronounced for horizontal links and when transmitting narrow beamwidth laser beams from the ground to space. Turbulence effects, scattering, and attenuation are all altitude dependent. At high altitudes, the effect is small for large telescopes, and turbulence along the path results in beam steering. Turbulence above the ground-based receiver results in wave front distortions in the form of a blur at the focal spot on the photodetector located behind the telescope. A significant portion of the atmospheric-induced optical link degradation can be allayed through proper site selection (Wojcik et al., 2005).

The atmospheric effects, singly or as an aggregate, can lead to dynamic attenuation of the signal strength. This phenomenon is referred to as signal fading. A fade is a transient condition that occurs when signal intensity at the receiver at any given instance is less than what is required to maintain the required link margin for a specified bit error rate (Andrews et al., 2001). Scintillation, spot dancing, and a time-varying speckle pattern at the detector are among major causes of fade events. The received signal fades away when a dark portion of the pattern overlaps the active region of the photodetector. Deep fades typically last 1–100 ms, depending on the strength of the turbulence effect for a particular link, and speed of the airflow across the beam driven by wind (Wojcik et al., 2005). In a high data rate optical link, significant amount of data could be lost during a fade period.

Fade mitigation techniques include use of large aperture diameters (greater than, approximately, 0.3 m), transmission of multiple beams that are mutually incoherent and physically separated (on the order of centimeters, use of long interleaver codes), implementation of adaptive optics technology, use of multimode lasers, and time or frequency diversity (Quaale et al., 2005; Moision and Biswas, 2007). As briefly explained below, each of these techniques suffers from implementation complexities or limitations.

For *downlink signal reception*, the *aperture averaging effect* (which becomes prominent when utilizing multimeter diameter ground telescopes) can mitigate scintillation effects on the beam and therefore decrease the fluctuations in total received power (Yuksel et al., 2005). Aperture averaging occurs when average size of the atmospheric turbulence cells is smaller than the diameter of the optical receiver. For *uplink beam transmission*, multibeam (4–16 beam) uplink can also mitigate some of the atmospheric turbulence effects on the beam (Wilson et al., 2007). For the multibeam fade mitigation to work, the laser beams have to be mutually incoherent and spatially separated enough to traverse uncorrelated atmospheric paths (Cameron et al., 2005).

Figure 8 shows that as much as 13 dB of the atmospheric fade depth can be mitigated via gains from implementation of long interleaver codes (Moision and Biswas, 2007).

Link availability is the fraction of time out of a year over which a laser communications link is operational. Link availability is highly dependent on the time of day and location of the telescope receiver site. Telescope site location options include space, platforms situated above clouds, and ground. Space-based receiving stations provide high link availability due to cloud-cover mitigation but suffer from limited aperture diameter and the lack of ability to upgrade and maintain the system after launch (Hurd et al., 2005; Biswas et al., 2006). High-altitude platforms avoid some of the drawbacks of space-based systems. But due to high winds that are typically encountered at those altitudes, these platforms are often challenged in providing lasercom-suitable

Emerging Technologies, Free-Space Optical Communications, Figure 8 Effect of interleaver in atmospheric fade mitigation is illustrated.

attitude-control levels. In the short term, ground-based receiver networks with atmospheric conditions limiting link availability provide an affordable solution. A recent study indicated that a network of five optical stations located globally will provide link availability of approximately 93 % (Link et al., 2004).

Optics: earth-based aperture

The Earth-based receiver collects the downlink signal photons and directs it to the photodetectors. Clearly, the larger the effective ground transceiver diameter, the greater the margin for the link. The excess link margin may be applied to shift hardware implementation burden away from the spacecraft (and onto the ground), to reduce flight system mass and power requirements, or to increase the amount of data delivered to Earth. The optical aperture may be a single telescope several meters in diameter or an array of distributed telescopes with meter-scale diameters. Each telescope may have a monolithic or a segmented primary mirror. Also, this transceiver may be located on the ground or at high altitudes above clouds, with clear advantages for each case.

The recent advancements in solid-state, very-low-noise, high-detection-efficiency photon-counting detectors (that operate near room temperature) have given credence to optical receiver architectures that utilize meter-class telescope diameters, each equipped on at least a 2×2 array of photon counters. Features of an array of telescope receivers are redundancy, graceful degradation, affordability scaled by the number of elements in the array, and potential for cost savings of a network of stations.

Figure 9 illustrates the schematic of a distributed and scalable ground receiver architecture.

The focal spot diameter of meter-scale diameter telescopes is set by the atmospheric turbulence-induced blurred conditions. The smallest achievable blur circle diameter for a downlink laser beam of wavelength λ that has traversed through an atmosphere with its seeing set by r_0 is set by an angle that is approximately $(r_0/\lambda)^2$ steradians (Roberts, 2005). Large-diameter membrane medium (10s of nm) band-pass optical filters (located at the entrance aperture of the telescope) and small-diameter narrow (sub-nm) band-pass filters, located just before the photodetectors(s), will combine to provide an essential level of background light rejection (Degnan, 1993).

Hybrid laser communications and precision laser ranging

An active laser-ranging transponder and laser communications transceiver have multiple-system-level requirements and subsystems in common. Steps necessary to operate a laser communications system in a transponder mode to infer millimeter-level range resolution are outlined below.

The interest in high-accuracy laser ranging to Mars is motivated by tests of relativistic gravitation, including the tests of the strong equivalence principle, Mars interior science (through exploitation of sensitivity to Mars precession, nutation, polar motion), and planetary science (through improvement of basic dynamical model parameters for the solar system). Centimeter-level resolution of Earth-Moon distance has been demonstrated via laser ranging to passive corner-cube retroreflectors deployed

Emerging Technologies, Free-Space Optical Communications, Figure 9 Scalable optical receiver followed by distributed decoder architecture.

on the lunar surface (Williams et al., 2009). Millimeter-level accuracy of lunar laser-ranging (LLR) data is expected in the near future (Turyshv and Williams, 2007; Murphy et al., 2007). However, due to the high space loss stemming from the $1/R^4$ energy transfer from passive corner cubes, passive laser ranging to planets is not possible at this time. Due to the benefit of $1/R^2$ energy transfer, active laser ranging to transponders located at the Moon or Mars will provide higher signal-to-noise ratios. The development of active laser-ranging techniques would extend the accuracies characteristic of passive laser tracking to interplanetary distances. Picosecond timing resolution time tagging of received and transmitted signal can now enable mm-class resolution ranging between the Earth and Mars.

A pulsed laser transponder system (based on time-of-flight measurements) is an efficient approach, requiring lower laser power than other available schemes and may be used in photon-counting mode without the need for phase referencing. A simple laser transponder might employ an “echo” technique, wherein the laser pulses from the remote unit are produced in response to detections of received pulses (Degnan, 1993). A more robust solution is paired one-way ranging, an asynchronous scheme in which both Earth and Moon/Mars stations transmit free-running pulse trains, time tagging all transmit and receive events (Degnan, 2002). Advantages of the asynchronous scheme include (1) noise immunity, the remote station does not transmit pulses in response to

numerous background photon detections; (2) stable laser performance, steady pulse generation results in thermally stable conditions; and (3) multiple Earth stations can range to the remote unit simultaneously without placing conflicting demands on the remote transmitter. With this scheme, clocks at each end of the link provide the baseline for time measurements, though only the Earth clock needs to keep absolute time. A frequency error in the remote clock is separable from velocity effects given multiple bidirectional measurements.

Despite the difference between beam pointing requirements for laser ranging and a lasercom transceiver, system-level requirements may be merged effectively to form a dual-functioning instrument serving both applications. Key differences between the two subsystems and methods to mitigate them are as follows:

1. Extensive transmit/receive isolation is typically required at each transceiver to maximize the link capacities of a bidirectional laser communications system. In a laser-ranging system, each transceiver must direct a portion of the transmitted light to its receiver in order to get an unbiased measurement of the transmit/receive time intervals.
2. Planetary communications links are typically designed for highly asymmetric performance, with a downlink data rate much higher than the uplink. A ranging system requires allocation of equal timing precision on each link.

3. The bandwidth and peak-to-average power ratio are chosen to maximize the data rate in a communications system. In a ranging system, a higher bandwidth always improves the precision at a given power, as does a higher peak-to-average power ratio in the presence of background light. Thus, a ranging system will typically require shorter laser pulses, higher pulse energies at lower repetition rates, and higher detector bandwidths (lower jitter).

Techniques to mitigate each of the above possible conflicts have been identified and are being implemented in the laboratory (Hemmati et al., 2009).

Summary

Technology of free-space laser communications at the component, subsystem, and system levels has advanced enough to successfully validate the lasercom technology at the maximum Mars range with data rates approaching 500 Mb/s – nearly two orders of magnitude beyond the state-of-the-art radio-frequency communications systems. There is opportunity for significant additional link margin improvement. When realized, the additional link margin may be used to reduce mass, power consumption, size, and complexity of the flight transceiver. The enhanced data rate capability will, for example, enable streaming high-quality video from other planets to the Earth. The “light science” enabled by lasercom (akin to radio science) remains a largely unexplored field.

Key remaining engineering challenges include circumventing attenuation due to dense clouds/fog, communicating while the receiver field of view is within a 1° of the Sun, and addressing the inadequacy of ground station infrastructure. While future Earth-based optical receivers may be located on airborne or Earth-orbiting platforms to circumvent atmospheric issues, technology and operational demonstrations for the first decade or so of deep-space laser communications will likely rely on lower risk and less-expensive ground-based receivers. Ground station diversity can adequately mitigate cloud cover. Large-diameter membrane filters located at the entrance aperture of ground-based telescopes, or telescopes designed to circumvent Sun interference, will aid with communications at small Sun angles. The advent of affordable, large-diameter, non-diffraction-limited ground telescopes should make infrastructure development realizable.

Synonyms

Ladar; Laser radar; Optical radar

Definitions

Lidar. Light Detection And Ranging.

Ladar. LAsER Detection And Ranging.

Introduction

The term *lidar* (i.e., the optical analogue of radar) embraces a broad collection of active optical probing techniques for remotely determining the physical and chemical characteristics of diffuse or condensed matter targets, both natural and otherwise. Although lidar methods have been practiced since before the dawn of the laser era, their classification here as an emerging technology reflects the fact that they have only in relatively recent years begun to see systematic exploitation from space-based vantage points (most especially with the advent of robust, high-performance laser systems).

Some remarks on terminology are in order as a guide to those unfamiliar with this field. Although the terms *lidar* and *ladar* are essentially interchangeable (except for exceedingly rare instances in which an incoherent source is used and which would therefore exclude consideration of *ladar*), different application communities have preferentially adopted one over the other. Hence, the atmospheric science community uses the form *lidar*, while those working in areas that involve remote characterization of hard targets have adopted *laser radar* or *ladar* (McManamon, 2012). It is also possible to find instances where *ladar* and *lidar* appear in upper case, reflecting their origin as acronyms. This is becoming less common now that these terms (like *radar* before them) have entered general parlance, but the hybrid form **LIDAR** is nevertheless commonplace albeit used exclusively by the airborne laser terrain mapping community.

A number of textbooks are available that treat lidar systems and methodology from a variety of standpoints. Measures (1992) provides a thorough grounding in the basic theory and practice of laser remote sensing, while Fujii and Fukuchi (2005), Weitkamp and Walther (2005), and Kovalev and Eichinger (2004) collectively offer a comprehensive overview of the wide array of measurement applications that have benefitted from lidar. Grant et al. (1997) provide an anthology of seminal lidar papers from the earliest days, when arc lamps were the brightest sources available, up to the mid-1990s.

Lidar basics

A canonical lidar system comprises the set of subsystems depicted in Figure 1. Depending on the intended application, the laser transmitter may require stringent control of wavelength, spectral purity, polarization, pulse duration, or some combination of all of these properties. By corollary, the receiver system may also be required to analyze one or all of these same properties of the return radiation.

Following the detection stage, processing electronics convert the signals to a range-gated (i.e., time-of-flight registered) data stream which is then logged for further processing to extract the desired observable quantity. This is accomplished through an understanding of the often complex interaction phenomenology of the laser radiation with the target and frequently leads to a suboptimally constrained retrieval process which must be augmented

Emerging Technologies, Lidar, Figure 1 Functional schematic of a generic lidar system.

by ancillary measurements, modeled parameters, or a combination of both. The optical power $P(R)$ returned to the lidar detection subsystem by a scattering volume located at range R is given by the standard basic lidar equation:

$$P(R) = \left[E\eta O(R) \frac{cA}{2R^2} \right] [T(R)T'(R)\beta(\lambda, R)], \quad (1)$$

where E is the pulse energy emitted into the atmosphere (outward transmission T , return transmission T'), A is the receiver collecting area, and β is the backscatter from the range element of interest at the specified emission wavelength, λ . η is the overall optical efficiency of the receiver subsystem and $O(R)$ is the range-dependent transmit/receive overlap function. (In general, the optical efficiency represents the optical transmission. However, for a *coherent* detection lidar system, this parameter will also include a component due to heterodyne mixing efficiency (Zhao et al., 1990).) The distinction made between outgoing and return atmospheric transmission recognizes that the incident radiation in some cases will be inelastically scattered, as explained below. Terms grouped together in the first set of square parentheses in Equation 1 are lidar system-dependent parameters, while those contained in the second set of square parentheses characterize the atmospheric response. This expression also assumes single scattering. Many lidar systems are subject to multiple scattering to a greater or lesser extent, and this will complicate the data inversion procedure. Eloranta (1998) provides a discussion of these issues and techniques for their resolution.

While pulsed operation is implicitly assumed in Equation 1, other forms of range gating have used modulation of continuous wave (cw) laser sources, such as pseudorandom noise encoding (Takeuchi et al., 1986), in conjunction with synchronous detection of the return to extract the time-dependent signal behavior.

Most, if not all, lidars are operated in the backscattering or quasi-backscattering configuration in which the transmitter and receiver are collocated and form part of an integral instrument. When the transmit and receive optical axes are coaxial, the lidar is said to be *monostatic*, whereas if they are offset, the lidar is described as *bistatic*. Note that this nomenclature differs from that applied in the radar field in that a bistatic radar system comprises transmitter and receiver elements that are geographically separated, whereas a monostatic radar implies collocated transmitter and receiver systems that may or may not be coaxial. Multistatic lidar configurations comprising two or more receiver stations have been considered for certain specialized applications (e.g., Olofson et al., 2008), but thus far, none have been implemented beyond the experimental stage.

An additional distinction that is frequently used to classify lidar systems is the mode of photon detection employed. In a *direct (incoherent) detection* lidar, the received photons are converted directly to electrical impulses by the detector with the loss of all phase information, and this is the detection method found in the overwhelming majority of lidar systems. In a *heterodyne (coherent) detection* lidar, the received photons are mixed with a reference oscillator signal and detection is performed on the intermediate frequency. Such a configuration is technologically more complex than a direct detection system, and also makes considerably more stringent demands on laser frequency stability and beam quality, but preserves phase knowledge and is essential if the ultimate goal is to directly retrieve motion-induced Doppler signatures, such as for atmospheric wind measurement (Huffaker and Hardesty, 1996) or object tracking (Osche and Young, 1996). A few coherent detection lidars have been described that are non-Doppler capable (e.g., Grant et al., 1987; Menzies and Tratt, 1994; Gibert et al., 2006). In these cases the additional system

complexity is tolerated because of the much greater noise rejection that is afforded by coherent detection, which can be as much as an order of magnitude above that of a comparable direct detection system (Menzies, 1976).

Inelastic backscatter lidar

Inelastic backscatter lidars make use of wavelength conversion properties of the target to infer details of its physical and chemical makeup. The chief downshifting processes that are commonly employed in the lidar field are Raman and fluorescence scattering, both of which require excitation in the UV-visible spectral range.

Although the weak cross sections for Raman scattering tend to limit its usefulness for long-range remote sensing purposes, this disadvantage is offset by the high specificity that it affords (because the observed wavelength shift is diagnostic of the molecule being probed). Hence, many users tolerate the need for a high-power transmitter, large collection aperture, and long accumulation intervals in order to gain the benefit of unambiguous measurements, which is clearly of central importance when such systems are used to validate satellite data products (Wessel et al., 2000; Tratt et al., 2005). Raman lidar has met with significant success in the ground-based remote sensing of atmospheric constituents and structure (Turner and Whiteman, 2006), atmospheric dynamics (Koch et al., 1991), and hazardous substances (Sharma et al., 2005) and has also seen limited airborne application (Heaps and Burris, 1996).

Fluorescence lidars are generally used for the investigation of chemical and biological targets. For example, laser-induced fluorescence has been successfully used in the remote assessment of plant health (Saito et al., 2000), airborne monitoring of phytoplankton populations and ocean productivity (Hoge et al., 2005), and the diagnosis of biodeterioration in building fabrics (Weibring et al., 2001). These techniques rely on measurement of the 690 nm chlorophyll- α fluorescence signature (sometimes in association with other features) and an understanding of the way it is modified by environmental disturbances. Fluorescence lidar has also been proposed for monitoring of marine oil spills (Karpicz et al., 2006) and the identification of airborne chemical agents or pathogens (Buteau et al., 2007).

So-called resonance fluorescence techniques, as the name implies, resonantly excite a target atomic species in order to directly probe the atmospheric properties at the residence altitude of the species in question, which are typically metal ions entrained in the middle and upper atmosphere (80–100 km altitude) that are derived from, and continually replenished by, meteoritic deposition. Hence, there is a long heritage of using sodium lidars to track atmospheric dynamics in these difficult-to-access regions (Gardner, 1989) as well as to retrieve upper atmospheric temperatures through measurement of the Doppler-broadened atomic lineshape, which can then be related directly to the ambient temperature. Other atomic metal species that have been studied for similar purposes

are potassium (Papen et al., 1995) and iron (Kane and Gardner, 1993). More recently, iron Boltzmann lidars have been used to infer atmospheric temperature by measuring the spectral content of radiation emitted by resonantly excited mesospheric iron layer atoms (Gelbwachs, 1994; Raizada and Tepley, 2002). An extensive treatment of this field has been given by Chu and Papen (2005).

An intriguing new class of inelastic backscatter lidar is the so-called femtosecond white-light lidar. This employs an ultrashort-pulse transmitter operating in the near-IR at around 800 nm whose high intensity gives rise to nonlinear self-phase modulation that results in broadband upconverted continuum emission across the UV-IR spectral range (Kasparian et al., 2005). The critical factor in such systems is that the broadband continuum is emitted predominantly in the backward direction and is thus a particularly strong and effective backscattering mechanism (Yu et al., 2001). Applications for the femtosecond lidar center on investigations requiring multiple wavelength channels to constrain multivariate retrievals, such as high-resolution atmospheric absorption spectrum measurement and aerosol composition and microphysics determination (Kasparian et al., 2003).

Elastic backscatter lidar

The majority of lidar systems in use can be broadly classed as elastic backscatter systems. Elastic backscattering processes conserve the centroid wavelength and consist of Rayleigh (or molecular) scattering from air molecules and particle scattering from suspended particulate material (aerosols and clouds). (The term Mie scattering is frequently used to implicitly denote particle scattering; however, the Mie descriptor strictly speaking only applies to scattering from *spherical* particles, which in general account for only a small percentage of the total atmospheric aerosol population.) Rayleigh scattering magnitude is inversely proportional to the fourth power of wavelength, which in practice limits the usefulness of Rayleigh lidar approaches to wavelengths not exceeding the visible spectrum. Rayleigh lidar systems tend to be used for profiling fundamental atmospheric properties such as temperature and density (Chanin and Hauchecorne, 1984).

By far the commonest application of lidar is concerned with cloud and aerosol (i.e., particulate) detection and characterization. In its simplest form, this can entail measurements at a single wavelength to infer the broad characteristics of scattering structure in atmospherically entrained dust and cloud features. However, in the absence of ancillary data, such minimally constrained measurements can only acquire estimates of attenuated backscatter. To properly retrieve aerosol optical properties and physical parameters requires a multiwavelength lidar approach and calls for backscatter coefficients at a minimum of three wavelengths and aerosol extinction coefficients for at least two wavelengths (e.g., Müller et al., 1998; Althausen et al., 2000). Aerosol extinction

has typically been obtained from collocated, contemporaneous column optical depth measurements (using sunphotometers) or from auxiliary Raman lidar channels, which measure the Raman backscatter from a well-mixed atmospheric constituent (usually nitrogen) and observe its departure from expected values to ascribe the aerosol extinction (Ansmann et al., 1992). However, in recent years there has been increasing interest in the high spectral resolution lidar (HSRL) technique because of its ability to separate and directly measure the aerosol and molecular scattering components with a single, self-contained multiwavelength instrument that avoids recourse to ancillary measurements (Eloranta, 2005; Hair et al., 2008).

In addition to the wealth of ground-based and airborne cloud/aerosol lidar systems that are today operated around the world, some functioning as components of autonomous, long-term monitoring networks, three multiwavelength systems have flown in Earth orbit, one on the Space Shuttle (Winker et al., 1996) and two on dedicated free-flying platforms (Spinhirne et al., 2005; Winker et al., 2007). There has even been a cloud/aerosol lidar operated on the surface of Mars (Whiteway et al., 2008).

Polarimetric lidar

The shape of cloud/aerosol particles can also modify the polarization state of scattered radiation. Polarization lidars exploit this phenomenon by separately measuring the unaltered (p) and depolarized (s) components of the return radiation, for which a range-dependent *backscatter depolarization ratio*, $\delta(R)$, can then be defined:

$$\delta(R) = \frac{P_s(R)}{P_p(R)}. \quad (2)$$

(Note, however, that Gimmestad (2008) has offered a recasting of the traditional polarization lidar formulation that is more descriptive of the microphysical processes involved and which may in time supersede this notation.)

The magnitude of the depolarization ratio can be used to deduce the degree of nonsphericity of the particles. The relative polarimetric properties of various aerosol and cirrus particles show sufficient diversity that polarization lidar can provide for some level of discrimination between the different classes of such particles (Sassen, 1991; Sassen, 2007). However, care must be taken when inferring scattering or attenuation coefficients from lidar measurements of cirrus, as the preferential horizontal orientation of cirrus platelets has been shown to dramatically enhance lidar returns through the addition of a specular reflection component to the backscatter signal (Platt et al., 1978). In order to separate the intrinsic cirrus scattering properties from this effect, it is therefore advisable to offset the lidar viewing angle by $\sim 3^\circ$ from the vertical.

Differential absorption lidar

The differential absorption lidar (DIAL) evolved as a means for identifying and quantifying gaseous

atmospheric constituents. The technique entails transmitting two different wavelengths, one tuned to a characteristic spectral feature of the target species and the other offset by a small but sufficient amount that it is unaffected by the target gas and so acts as an atmospheric transmissivity reference. The usual practice is to contrive the on- and off-resonant wavelengths to be as narrowly separated as possible (in order to eliminate dispersive effects from other atmospheric constituents that could confuse the measurement), so that the following close approximation for the number density $N(R)$ of absorbing molecules can be applied:

$$N(R) = \frac{1}{2|\sigma|} \frac{d \ln [P_{on}(R)/P_{off}(R)]}{dR}, \quad (3)$$

in which σ is the differential absorption cross section between the on- and off-resonant wavelengths.

A large number of DIAL systems are in operation worldwide to measure a wide variety of atmospheric trace gases from the ground and from the air. Because of their climatic impacts, water vapor and ozone profiling are two common DIAL measurement objectives (Browell et al., 2004), while a plethora of systems operating from the UV to the thermal-IR are in use to track the transport and dispersion of plumes containing common pollutants such as sulfur dioxide (Weibring et al., 1998), ammonia (Zhao et al., 2002), hydrocarbons (Murdock et al., 2008), and many other compounds.

The ongoing debate over the role of carbon dioxide in climate change has driven a resurgence in interest concerning DIAL techniques for monitoring this atmospheric constituent. The requirement is for mixing ratio measurement globally throughout the lowermost levels of the troposphere with a precision of $\sim 0.5\%$, which is considerably more challenging than the typical $\sim 20\%$ DIAL precision specification. Conventional DIAL is one of two approaches that are under evaluation for this application (Koch et al., 2004; Gibert et al., 2006), the other being integrated path differential absorption (IPDA), which entails cw or quasi-cw illumination of the Earth's surface at on- and off-resonant probe wavelengths (Menzies and Tratt, 2003). The retrieved differential absorption return can then be transformed into a path-averaged column content (Abshire et al., 2010; Spiers et al., 2011). Detailed trade studies will ascertain the optimum wavelength combination and detection configuration for acquiring high-precision gas mixing ratios by this technique.

Doppler lidar

Doppler lidars are used to measure target motion, either for atmospheric wind measurement (Baker et al., 1995) or object tracking (Osche and Young, 1996), and can be divided into two distinct classes. *Coherent detection Doppler lidars* directly measure the Doppler shift imposed on the optical return by the atmospheric target by mixing the return signal with a well-defined frequency reference

laser, termed a *local oscillator*. The heterodyne mixing efficiency in such systems is a sensitive function of frequency purity, wave front quality, and optical aberration factors, any one of which can be the source of significant performance degradation if not adequately managed (Zhao et al., 1990; Chambers, 1997). For hard target coherent Doppler lidar systems, where backscatter is high, these considerations are less of an issue, but for atmospheric applications, where performance is contingent on aerosol and cloud backscatter, one is effectively driven to operating wavelengths in the IR spectral region.

By contrast, *direct detection Doppler lidars* operate in the “photon bucket” mode and thus do not mandate the wave front quality requirements of coherent systems. In a direct detection system, the Doppler shift is inferred indirectly by measuring the differential transmission of the return signal through a high-resolution filter mechanism whose dispersion characteristics must be known to high accuracy and very well controlled. Freed from the IR wavelength constraint to which coherent systems are subject, direct detection Doppler lidars are thus designed to take advantage of the omnipresence of molecules in the atmosphere by operating in Rayleigh backscatter mode (usually in the eye-safe UV). Direct detection systems are less photon efficient than their coherent counterparts, and their retrieval accuracy can be compromised by the individual and collective stability of optical components within the receiver subsystem, but are preferred for operation against atmospheres that have little or no aerosol content. The combining of both Doppler lidar approaches in a *hybrid* instrument has been suggested as a means to make best use of the advantages of both types of system (Emmitt, 2004).

There is a significant body of experience with both surface-based (Huffaker and Hardesty, 1996; Grund et al., 2001; Henderson and Hannon, 2005) and airborne (Bilbro et al., 1986; Rothermel et al., 1998; Werner et al., 2001; Hannon et al., 1999) coherent Doppler wind lidars. In addition, there have been several ground-based direct detection Doppler wind lidars (von Zahn et al., 2000; Gentry et al., 2000; Irgang et al., 2002) and also a few airborne systems (Dehring et al., 2006; Durand et al., 2006). All require some means of scanning the transceiver in order to obtain the multiple perspective line-of-sight retrievals that are necessary to resolve 2D or 3D wind vector fields.

The European Space Agency (ESA) plans to deploy the first space-based Doppler lidar. The Atmospheric Dynamics Mission (ADM-Aeolus) will carry a direct detection Doppler wind lidar and an integral high spectral resolution lidar (HSRL) with two receiver channels for analysis of aerosol/cloud backscatter and molecular backscatter, respectively (Stoffelen et al., 2005). This instrument will address only a single off-nadir line-of-sight perspective but will nevertheless represent the first on-orbit demonstration of Doppler wind lidar techniques.

It is worth noting here that the first lidar wind measurements from space were made by a non-Doppler elastic backscatter system using optical scatterometry of the

ocean surface (Menzies et al., 1998). These measurements were necessarily indirect, scalar in character, and restricted to sea surfaces only, but more recent measurements indicate that this approach can provide significant new information on ocean winds and associated air–sea interaction processes (Hu et al., 2008).

Laser ranging and geodetic imaging

Laser ranging to hard targets was among the earliest of lidar applications and has seen by far the most commercial exploitation. Apart from the proliferation of laser-augmented rangefinding binoculars and surveying instruments, the technique is now in high demand for airborne high-density terrain mapping (Slatton et al., 2007) and shallow-water hydrographic surveying (Banic and Cunningham, 1998), for which a significant commercial services capability has arisen. Laser altimetry was also the first lidar application to be implemented in space (Sjogren and Wollenhaupt, 1973; Bufton, 1989; Garvin et al., 1998), and global-scale geodetic mapping by laser altimetry can in many respects be regarded as commonplace, having now been demonstrated with moderate horizontal resolution (10–100 m) on Earth (Schutz et al., 2005), Mars (Smith et al., 2001), Mercury (Zuber et al., 2008), the Moon (Smith et al., 1997; Smith et al., 2010), and the irregular asteroids Eros (Cheng et al., 2002) and Itokawa (Mukai et al., 2007). Most of these were first-return time-of-flight instruments, the exception being the Geoscience Laser Altimeter System (GLAS), which was designed to transcribe the entire return waveform (Abshire et al., 2005). Full waveform recovery makes it possible for laser altimetry to resolve volumetric vegetation structure and sub-canopy topography by taking advantage of the optical porosity of vegetation cover (Blair et al., 1999; Lefsky and McHale, 2008).

Some measurement scenarios call for a level of areal density of individual ranging measurements that pushes horizontal resolution toward the meter range. For these applications, limited pulse energy and the need for rapid scanning mean that “photon starvation” becomes a significant issue (Abrams and Tratt, 2005). To address this concern, single-photon counting detector arrays with integrated readout circuitry have been developed to acquire 3D imagery of laser flood-illuminated scenes in what is often termed a *flash lidar* scheme (Albota et al., 2002). In addition, work is currently in process to extend active image formation techniques from the established synthetic aperture radar domain into the optical spectral region (Beck et al., 2005). This technique faces nontrivial technical challenges but is nevertheless being pursued for tactical applications (Ricklin and Tomlinson, 2005) and has also been proposed for planetary remote sensing (Karr, 2003).

High-density laser ranging is also used in space-to-space scenarios where the uncompromising demands of autonomous rendezvous and proximity operations rule out less precise instrumental approaches (Nimelman et al., 2006).

Summary

Active optical remote sensing (lidar) techniques have provided demonstrable enhancements in spatiotemporal resolution and reduced dependence on the diurnal cycle in comparison to other remote sensing methods used for Earth and planetary science applications. While the breadth and diversity of lidar methodology attests to its fundamental versatility, there are certain measurements that are enabled uniquely by active optical sensors (e.g., aerosol and cloud vertical structure, global-scale tropospheric wind measurement, 3D vegetation structure, high-resolution sub-canopy topography mapping). The intrinsic benefits of lidar now drive a steadily increasing number of fielded systems on the ground, in the air, and in space. While not exhaustive, this entry describes the basic characteristics and associated applications of the commonest types of lidar likely to be encountered and also provides an introduction to some promising emerging concepts that have yet to fully mature into accepted field-capable systems.

 Technology, Pasadena, CA, USA

Definition

To respond to the wide range of goals in Earth and Planetary sciences, radar systems must operate with a wide range of functionality. Parameters include multipolarization transmit and receive signals, multiband operation, adaptable resolution, scanning for increased swath, and very high measurement accuracy. In addition onboard data processing

techniques for data reduction and transmission and handling of large data sets are increasingly important as more complex, higher bandwidth radars are needed to meet mission requirements. Improved tools and support for warehousing and data mining are required to document the large number of missions and retain long duration data records required to perform key analysis, modeling, and monitoring.

Lowering mass and volume of radar systems is especially important for spaceborne missions both to lower spacecraft and launch vehicle costs and to enable combining multiple instruments such as radar/lidar on the same platform. Continued technology advancements focusing on risk and cost reduction are also critical.

Below are some of the technologies for future radar systems:

RF technologies

High-efficiency RF semiconductor devices are critical for future high-power systems. The use of wide bandgap semiconductors technologies such as GaN technology enables high-power, high-efficiency power amplifiers. For the most part, this technology can replace other devices, such as Si and GaAs, in power amplifier components.

In addition to semiconductor technology, some applications will still require the use of extended interaction klystron (EIK) and/or traveling-wave tubes (TWT). Further technology advancement in phase stable, higher peak power, higher efficiency, and longer life devices is needed.

Device technologies such as SiGe allow integration of RF and digital components onto the same chip enabling the concept of "radar on a chip." This is most beneficial for phased array applications where we need hundreds or thousands of these transmit/receive (TR) modules for electronic beam scanning.

In addition to high-efficiency, high-power RF transmitters, phase stable electronics both for receive and transmit are critical for future interferometry applications.

Quasi-optical techniques at millimeter-wave frequencies must be improved to support the front-end optics/electronics for millimeter-wave radars measuring crucial environmental parameters, such as clouds, aerosols, particulates, and other pollution.

Antenna technologies

In most cases the largest part of a radar is its antenna. Developing new materials and technologies for reducing antenna mass density both for passive and active antennas is critical. For reflector-type antennas, mesh technology is currently used at lower frequencies. Future radars will need larger mesh antennas at high frequencies (ka-band above). For these radars the development of multi-frequency shared feeds will allow sharing of resources for multiple measurements.

For very large active-phased arrays (size of 900 m² or greater), membrane technology is one way of reducing

mass density. Technology challenges in this area include integrating electronics with the array, manufacturing of these arrays, reliability, and the need for calibration to account for the antenna shape change.

MEMS technologies

MEMS resonators have the potential to incorporate low-loss front-end analog filtering into active antennas. This technology is becoming more important as the RF spectrum becomes more crowded, and digital processing is moving up the RF chain. As MEMS technology matures, other MEMS technologies such as MEMS switches might be usable in radar front-end electronics.

Digital technologies

Analog-to-digital converters (A/D) transform continuous analog radar signals into discrete digital signals. Extensive use of digital signal processing of radar data demands higher sampling rate A/D converters with larger dynamic range. Direct sampling of higher frequency signals, such as L and S band, requires faster A/D converters as well as higher dynamic ranges.

Due to further advancements in digital electronics, radars are using digital techniques in areas that RF technologies were previously used. One of these areas is the use of digital filtering, for example, for RFI mitigation. This allows the filtering of unwanted signals as the radar moves in space encountering different in-band interference. Another area where digital technology is replacing RF is digitizing higher frequency signals without having to downconvert the signal. For example, with current technology an L band (1.2 GHz) direct digital receiver is possible.

Another area which will dominate future radar applications is adaptive onboard science data processing. This along with development of a direct downlink capability provides near real-time data products tailored to users' needs.

Information system technology

We will need information technology advances for collecting, handling, and managing very large amounts of data and information in space and on the ground. These advanced information systems need to support new observations and information products; increase the accessibility and utility of science data; and reduce the risk, cost, size, and development time for future missions. These technologies are not unique to radar systems but apply to all sensors. However, radar systems typically collect large data which can take advantage of these processes. Technologies in this area include incorporating autonomy and intelligence within the sensing process and allowing rapid response to needed measurements, data acquisition on demand (in response to both science and society), sensor-to-sensor coordination, and interoperability. These technologies will increase the effectiveness of observing instruments or missions.

We also need technologies for combining observations of multiple Earth science variables into numerical models, data mining for information characteristics or content, dynamically acquiring and combining data from multiple data sources and distributed processing.

Constellations

Improved orbital control and tracking, along with satellite-to-satellite communication, is required to continue trends.

EMERGING TECHNOLOGIES, RADIOMETER

Todd Gaier

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA, USA

Definition and introduction

Radiometric remote sensing involves the detection of emitted radiation and or reflected ambient radiation from an object. Such radiation typically originates as blackbody radiation from a remotely sensed object, undergoing partial reflection or absorption by intervening media. Detection is generally categorized into two types, *coherent detection* or *incoherent detection* (often referred to as direct detection). Coherent detection preserves the phase of the incoming wave, while incoherent detection does not. Examples of incoherent detectors include bolometers, thermopiles, CCD and APS sensors, as well as photoconductors and power detection diodes. Most passive remote sensing applications do not require phase preservation, although the advantages of phase-preserving detection make these systems the preferred choice for environmental applications in the frequency range

Emerging Technologies, Radiometer, Figure 1 Schematic of a basic radiometer suitable for remote sensing.

Emerging Technologies, Radiometer, Figure 2 Photograph of the Jason-II advanced microwave radiometer, 34 GHz channel, which shows all of the major components of a remote sensing radiometer (Courtesy D. Dawson).

1 GHz–1 THz. It is important to note that direct detectors do not have to impart additional noise to the incoming radiation, although practically speaking, cryogenic cooling of direct detectors is required to eliminate this added noise. When the observed object is very cold and the detected signals are very small (as in applications in radio astronomy), direct detection provides the lowest possible noise. The cooling requirement and the fact that most objects observed in remote sensing applications are already warm, resulting in a large inherent noise term, make these detectors less desirable than coherent detectors. For the rest of this entry, the discussion will be limited to coherent detection.

The basic coherent detection radiometer system can be divided into a front end and a back end. The front end amplifies the incoming signal (a voltage waveform) to a level where additional signal processing can occur without consideration of additional noise. The front end usually performs this function with the lowest possible additive noise available, but coherent systems always add some noise. The back end processes the amplified waveform extracting the desired information. Since most electronic components used in these systems exhibit inherent long-term instability, some sort of regular

calibration or signal modulation must be applied to the radiometer. A schematic of a basic radiometer is shown in Figure 1. A photograph of an integrated radiometer is shown in Figure 2.

Radiometer front ends

The choice of front-end technologies depends upon the application and the frequency of operation. Below 100 GHz low-noise amplifiers are readily available. Most modern amplifiers use solid-state semiconductor, three-terminal devices (transistors) as the active low-noise element. The development of these transistors has a remarkable history which is driven largely by demands in the computer and telecommunications industries. Common transistors can be classified into two types: bipolar transistors and field-effect transistors (FETs). One can think of a bipolar transistor as a current-controlled current source (i.e., the input current between one terminal and the second controls the current between the second and third terminal). The action of the current control can be used to make a small signal larger, referred to as *signal gain*. A FET is a voltage-controlled current source (i.e., the *voltage* between the first and second

terminals determines the *current* between the second and third). At frequencies below a few GHz, bipolar transistors offer excellent noise and are extremely stable over time. These devices are typically made of doped silicon or sometimes (gallium arsenide) GaAs. Recently, the computer industry has pushed the practical frequency of operation of bipolar transistors well beyond 10 GHz. This is largely due to the development of SiGe transistors. SiGe transistors provide competitive gain and noise up to 10 GHz (Weinreb et al., 2007), at costs of pennies per transistor. This technology is also important for receiver back ends as will be discussed later.

The other primary front-end amplifier technology is a type of FET called a high-electron-mobility transistor (HEMT). HEMTs are devices in which the semiconductor crystal structure is grown one atomic layer at a time. This confines the current carriers (either electrons or “holes”) to a two-dimensional surface, relatively free of scattering, providing a combination of high speed (with resulting high-frequency gain) and low noise (Duh et al., 1988).

A second key development in this field is the ability to create very small *gate* structures. The gate is the terminal of the FET which controls the current. In order to obtain very high switching speeds, the time for a carrier to transit the gate must be short. Electron-beam lithography allowed the creation of gate structures well under 1 μ in size (0.1 μ is readily achievable today). HEMTs using GaAs semiconductors have been used to build low-noise amplifiers for decades at frequencies up to 100 GHz. In the 1980s, HEMT technologies were employed in monolithic microwave integrated circuits (MMICs) in which several transistors were integrated onto single chips functioning as amplifiers. During the 1990s, experiments were performed with different materials systems. Indium phosphide (InP) emerged as a materials system with very high gain, low noise, as well as low operating power. InP transistors and MMICs are now regularly used in systems up to 100 GHz with *noise temperatures* below 300 K (Pospieszalski, 2005; Lai et al., 2005).

Recent developments in this field have shown that it is still improving. Techniques have become available to reduce gate sizes as small as 35 nm. InP MMIC amplifiers have now been demonstrated at frequencies as high as 350 GHz (Pukala et al., 2008). These very high operational frequencies had been impossible for devices with gain. For remote sensing applications above 100 GHz, it has been typically required to utilize *heterodyne detection*. In a heterodyne receiver, the incoming signal is fed into a nonlinear device (usually a diode) where it is *mixed* with a sinusoidal voltage at almost the same frequency (local oscillator or LO frequency). A waveform results which has an amplitude proportional to the incoming signal but at a frequency which is the difference between the signal and LO frequencies. The heterodyne architecture is extremely useful if the observed object has high-spectral-resolution features, such as high-altitude atmospheric molecular line emission and absorption (Waters et al., 2006).

Diode mixers are the dominant radiometer front end between 100 GHz and 1 THz. Most of these diodes are Schottky diodes, formed when a metal and a semiconductor are brought into contact. Schottky diode mixers have been built up to several THz and have been used extensively in astronomy and atmospheric chemistry. The earliest mixers were built by manually pressing a metal whisker onto a piece of doped semiconductor. While these devices were used at very high frequencies, there were obvious reliability issues. Semiconductor and lithographic processes, similar to those used for transistors, are now used to make planar diode structures, also operating at THz frequencies. These planar devices can even be bought commercially. To obtain the lowest possible noise, mixers can be fabricated from superconducting devices called superconductor-insulator-superconductor or SIS mixers. While these devices have noise limited only by quantum mechanics, they require cryogenic cooling, making them impractical for many remote sensing applications. SIS mixers are widely used in radio astronomy (Pan et al., 1989).

Local oscillator technologies are a key part of heterodyne receiver front ends. Detection of signals at several hundred GHz requires oscillators working at these frequencies. For a long time, the primary device used was the Gunn-effect diode. Gunn diodes have a negative resistance, that is, as the voltage is decreased, the current increases. Such a device is inherently unstable. When coupled to a resonant cavity, this instability leads to oscillation, with the frequency of oscillation dependent upon the size of the cavity. Gunn oscillators capable of generating tens of megawatts have been built up to 160 GHz. To obtain even higher frequencies, diode frequency multipliers are employed.

Advances in power amplifier technology have enabled power generation at ever-increasing frequencies. GaAs power amplifiers are capable of generating hundreds of mW at frequencies above 100 GHz. These amplifiers have largely displaced Gunn oscillators as the primary source of LO power in mm-wave radiometers.

Calibration and modulation

The inherent gain instability of high-frequency circuits creates the need to stabilize the radiometer. The most common form of signal stabilization is the Dicke-switched radiometer (Dicke, 1946). The Dicke radiometer has as a first element, a modulation switch which rapidly exchanges the input signal with a stable reference load. The output of the radiometer is then a synchronous signal representing the remote sensed object and the reference load. Differencing of these signals on short timescales provides a calibration on a timescale shorter than the receiver gain can vary. A graphical depiction of this is shown in Figure 3. Many variations of modulated radiometers exist, including noise-adding radiometers (in which a noise source is added synchronously to provide gain calibration) and correlation radiometers (which allow for simultaneous

Emerging Technologies, Radiometer,

Figure 3 Pseudocorrelation Radiometer output. A time series (roughly 1 h) of data are shown with the radiometer alternately viewing a “remote sensed target” (*even*) and an internal reference load (*odd*). Each of the data sets displays long-term noise (due to gain instability). The differenced data are also shown, with considerably lower resulting noise and greatly improved stability. This demonstrates the power of signal modulation in a radiometer in removing time-correlated excess noise (Graphic courtesy M. Seiffert).

detection of two input signals through a common signal path). For each of these systems, signal modulators are required.

In order to be effective, switches used for Dicke modulation are usually in front of the first gain element. Historically, switches have been mechanical, ferrite, or semiconductor diode switches. Because of the high speeds and reliability required, mechanical switching is now limited to radiometers which can have the entire optical and receive system quickly scanned across the observed field of view. Ferrite switches use the time asymmetric properties of magnetic fields to switch signals between two ports of a three-port switch. The magnetic field of a circulating switch is typically provided by an electromagnet. Reversing the current in the electromagnet reverses the magnetic field which switches the microwave signal at a common port. In recent years, diode switches have been used for signal modulation. These switches take advantage of the conducting versus nonconducting states of a diode depending upon their *bias* or DC current. PIN (*p*-intrinsic-*n* doped semiconductor) diodes are particularly useful as switches as they are small, low loss (at low frequencies), support fast switch rates, and are repeatable and reliable with no moving parts.

PIN switches can also be used to make phase modulators. Phase modulators are useful in providing radiometer stability in a correlation (or pseudocorrelation) radiometer. In a correlation radiometer, couplers are used to provide a common signal path for incoming signals and the stable

reference. While they do share a signal path, these signals must be separated prior to detection, which creates residual instability. Phase modulation stabilizes this residual by switching the remote sensed and reference signals prior to detection. The advantage of such a system is that the modulation element need not be located prior to the first gain stage, which in turn means that signal loss is not a primary concern. PIN diodes tend to have high loss at high frequencies. For this reason, high-frequency radiometers often use correlation techniques for stabilization (Jarosik et al., 2003).

The noise-adding radiometer is also used to stabilize a signal. While it seems counterintuitive to add noise to a receive system, it is an effective means of providing necessary gain stabilization. In this system, a noise source is coupled into the receiver input (with low efficiency) and is rapidly modulated. The noise source is typically a noise diode (similar to a Zener diode), which is operated alternately in the off state and in a state near avalanche. In avalanche, the diode carriers undergo ballistic collisions with the lattice to produce excess noise. This white noise looks like a blackbody of high temperature (typically thousands of degrees kelvin). By coupling in a small portion of the signal, a stable offset of tens of kelvin can be generated, which, while small compared to the receiver noise, is large enough to provide long-term gain stabilization. Because of the statistics of the noisy signal, gain adding alone is typically insufficient to provide stability and is typically used with some other form of signal modulation.

Radiometer back ends

The back end receives the amplified input signals and performs necessary processing. In the simplest form, the back end is a band definition filter and a power detector. Such a system measures the *radiometric temperature* in a band. Power detectors for remote sensing systems are almost always either Schottky barrier diodes or tunnel diodes. The diode rectifies the incoming signal with a DC voltage response that, to first order, is proportional to the square of the voltage or the power. In order to rectify such high-frequency signals, it is necessary for the diode to have a fast response. Because Schottky diodes can be fabricated with small features, they are typically used for detection applications at frequencies above 10 GHz. Limitations of the diodes include post-detection instability and significant temperature dependence. For this reason, tunnel diodes are the preferred choice below 10 GHz. There have been recent developments in high-frequency tunnel diodes (Moyer et al., 2008), although little data exist for their application in remote sensing. Detector diodes typically output signals at the 1 μ V level in order to maintain linearity. The noise fluctuations about this signal are typically three to five *orders of magnitude smaller* than this, requiring low-noise *video* amplification (the term *video* is typically used to denote the post-detection signal).

Modern back-end processors take advantage of emerging digital technologies. Some of these back-end processors include *spectrometers*. A spectrometer takes the amplified input signal (or mixed signal) and processes the electromagnetic spectrum to determine the power in discrete frequency bands. As digital signal processing speeds improve, more technologies are becoming available for remote sensing applications. Digitizers with speeds faster than 2 GS/s are now commercially available. Processors also exist to handle these data rates. Field-programmable gate arrays (FPGAs) have been used to process these high-speed signals both in time and frequency domain. Spectrometers have been demonstrated using Fourier transform and polyphase filter bank technologies (Parsons et al., 2006).

The same technology can also be used to purge data of radiofrequency interference (RFI). RFI is becoming a greater problem for remote sensing applications in the frequency range 1–15 GHz as commercial communications technologies become widespread. Even with protected bands, contamination of the electromagnetic spectrum requires active monitoring and vetoing by current remote sensing experiments. Fortunately, the statistics of RFI signals differ from thermal signals, allowing for high-speed processing to flag and remove contaminated data (Ruf et al., 2006).

The final type of back-end digital processor is the cross correlator. The correlators multiply signals from one receiver with another. These signal products can be used in aperture synthesis interferometry. Aperture synthesis radiometry has become more widely used in recent years as large apertures without moving parts are becoming required to meet remote sensing requirements for soil moisture and ocean salinity measurements as well as continuous observations of atmospheric (SMOS, GeoSTAR).

Definition

Sensor webs are networks of sensors that can operate in a coordinated fashion, for example, through centralized or decentralized control centers. The controller can command the sensor nodes to modify their measurement schedule or configuration in response to environmental factors or to achieve certain measurement goals. Sensor webs are envisioned as a means of providing spatially and temporally adaptive in situ measurements for validation of remote sensing observations.

Introduction

Satellite remote sensing often results in data and retrieved geophysical products with resolutions that are significantly coarser than the scale of variations of the phenomena they represent. As an example of a geophysical variable, soil moisture fields retrieved from satellite observations using microwave instruments have resolutions on the order of kilometers if not coarser. However, the soil moisture fields themselves have spatial dynamics at the scales of several meters (e.g., because of topographic and land-cover variations), hundreds of meters (e.g., because of land-cover and soil texture variations), and kilometers (e.g., because of precipitation). Therefore, the coarse-resolution retrievals at the satellite pixel scale may not accurately represent the true mean of the soil moisture field.

The validation of satellite retrievals is therefore a challenging task. It requires the use of in situ sensor networks, whose node placement has to be such that the proper spatial statistics are represented and such that the in situ estimate of the mean soil moisture within the coarse-resolution pixel is close to the true mean. Furthermore, the measurement schedule of the sensor nodes has to be such that the temporal variations of soil moisture are properly captured. At the same time, it has to be dynamic so that, if necessary, only the minimum number of measurements is taken so that energy usage is optimized by the network.

A large number of sensor nodes may be necessary to sufficiently represent the spatial variations of the coarse-resolution field. For example, for the NASA Soil Moisture Active and Passive (SMAP) satellite mission, scheduled for launch in 2014, the primary soil moisture product will have a resolution of 10 km (Entekhabi et al., 2010). Depending on the topographic, vegetation, and soil texture heterogeneity present in various pixels, tens or hundreds of sensors might be needed for proper retrieval validation. However, it is not feasible to deploy such large number of sensor nodes with conventional data loggers and manual data collection schemes. Instead, wireless network concepts have to be used that allow near real-time data upload. There are many challenges with such large-scale outdoor networks, including energy management, lifetime, environmental robustness, network capacity, and costs. Such challenges

are illustrated by the following discussion involving the design of the sensor web for the SMAP mission.

Global architecture of the sensor web

The global architecture of the in situ sensor network is shown in Figure 1. The system consists of a field element and a home/office element. A wireless sensor network is deployed over a target field, along with a base station that performs data collection and sensing control, and a database collocated with the base station for local data storage. At each sensing site, several sensors (for example, soil moisture sensors) are deployed at different depths and connected to the sensor node (i.e., a ground wireless module). The base station receives data wirelessly from each sensor node; it can also control their measurement schedules on demand. It also periodically (every half an hour) uploads the collected sensor data through a long-range link, such as a 3G connection, to a database server located in the home base.

Initially, this network was built using the ZigBee (IEEE 802.15.4 plus higher layer specifications) standard (Moghaddam et al., 2010). The first deployment of this network was in a field near Canton, Oklahoma. ZigBee was chosen as it allowed the formation of a multi-hop network and due to its mature technology that could significantly shorten the development and production cycle. The disadvantage was that a router node under the ZigBee specification could not be put to sleep mode, thus consuming significantly more energy and requiring large batteries and large solar panels. It also was proven to be rather unstable for outdoor field environment due to poor router-base station connection, causing end devices (or nodes) to switch parent-child association. Therefore, the architecture was modified to adopt a two-tiered hierarchy: the lower layer consists of a local coordinator (LC) node and multiple sensor nodes or end devices (ED) associated with the LC node. The upper layer consists of LC node(s) and a base station. In contrast to existing network routers, the LC node can sleep and its energy requirements are significantly reduced. The LC node may be equipped with two radio interfaces, allowing it to communicate within the two layers using different radio technologies, effectively making the two layers logically separated. The lower layer uses the IEEE 802.15.4 standard but not

Emerging Technologies, Sensor Web, Figure 1 Global architecture of the wireless sensor network system.

Emerging Technologies, Sensor Web, Figure 2 A large wireless sensor network may have multiple local coordinators servicing a variety of different landscape types. Choice of local transceivers should be transparent to the network for extensibility.

the ZigBee suite. The advantages of this design include (1) flexibility in developing an open protocol on top of 802.15.4 for the lower layer and multiple candidate solutions for the upper layer; (2) the logical separation between the two layers, making sleep scheduling of the ED nodes much easier to control; (3) a different radio solution for the upper layer, allowing the system to span over much longer distances; and (4) ease of scaling up of system architecture. Using this design, the network can be scaled up (Figure 2) to contain multiple local coordinators that can be deployed in multiple landscape types and to cover a span of several kilometers.

Sensor placement, scheduling, and field mean estimation

The true mean of geophysical variables such as soil moisture fields is a function of time and of the state of the soil surface. Its determination ideally would require a very fine sampling of the remote sensing satellite footprint, both spatially and temporally. This, however, is cost prohibitive; manually installing these sensors is expensive, and their battery power does not allow us to continuously sample, as we need them to last a reasonably long period of time (months or even years). These considerations pose severe limitations on how many sensors can be made available and how frequent they can be used/activated. The overall objective is thus to place and activate sensors such that the field mean may be estimated to a desired accuracy subject to budgetary constraints, e.g., the total number of sensors available, the total amount of available energy at each sensor, and bandwidth (Wu and Liu, 2012a).

There are two elements to the above problem: one is the determination of the best set of locations within the sensing field to place a limited number of sensors (sensor related cost constraint) and the other is the optimal dynamic operation of these sensors (when and which to activate) once they are placed (energy constraint).

These two elements are coupled. For instance, if energy of operation is a bigger concern than placement costs, then one can choose to place more sensors to compensate for a desired, reduced sampling rate. The reverse holds as well. In addition, activation and sampling decisions can influence where sensors should be placed and vice versa. But jointly considering and optimizing both elements leads to a problem whose complexity is prohibitive both analytically and computationally.

For a given placement plan, the sensor measurement scheduling problem becomes one that aims to minimize the estimation error (for the reconstructed soil moisture process using measured samples) subject to a certain energy/sampling rate constraint, or to minimize the sampling rate subject to an estimation accuracy criterion, or to minimize certain weighted sum of both. The estimation can be done both in a closed-loop fashion and an open-loop fashion. Under a closed-loop approach, temporal and spatial statistics of the soil moisture evolution is first learned using training data (either real or simulated). This knowledge, which describes what is likely to happen given what has already happened, together with samples already collected, i.e., what we know has happened, can help predict the future and thus make judicious decisions on the best time to take the next measurements. This is essentially the idea behind a partially observed Markov decision process (POMDP) formulation of this problem (Shuman et al., 2010).

Emerging Technologies, Sensor Web, Figure 3 Recovery accuracy of compressed sensing approach under three types of measurement schedules (US: uniform/periodic sampling; RS: random sampling; GS: Gaussian sampling; TV: true value).

Under an open-loop approach, recent results from the theory of compressive sensing can be applied. This technique exploits an underlying sparsity feature of the measured signal and is able to reconstruct the soil moisture process from a very small number of samples to great accuracy. Advantages of this approach include the following: (1) it does not require training or a priori statistical knowledge of the soil moisture process, (2) the sampling sequence (measurement times) can be completely determined offline and in its simplest form can be a periodic sequence, therefore making implementation very easy, and (3) the same signal reconstruction technique can be used if we augment the sampling sequence with exogenous information like rainfall (e.g., take more samples during a rainfall event and less during dry periods). The figures below show the recovery accuracy of this approach under three types of measurement schedules (US, uniform/periodic sampling; RS, random sampling; GS, Gaussian sampling; TV, true value) (Wu and Liu, 2012b) (Figure 3).

Energy management schemes

Flexible energy management solutions are needed to meet the lifetime requirements of remote sensing missions such as SMAP. In doing so, increased reliability and reduced cost of wireless sensor network operation, extensibility to a large variety of target environments, and therefore an open and generalized architecture solution are needed.

Past experience has shown a significant number of battery failures caused by extreme temperatures as shown in Figure 4. Therefore, for many realistic deployment

Emerging Technologies, Sensor Web, Figure 4 Sensor nodes based on solar panels and rechargeable batteries typically have problems associated with sub-zero temperatures.

Emerging Technologies, Sensor Web, Figure 5 A Ripple-2 node powered by non-rechargeable batteries (top) installed in SoilSCAPE field locations such as Canton, OK, USA (bottom).

scenarios, the estimated lifetime of two or more years for a sensor node cannot be realized with rechargeable batteries because of their temperature sensitivity. Non-rechargeable batteries are the best option in this regard because of their tolerance to both high and low temperatures. If the usage of the network is consistently maintained low, such an approach could be very cost-effective and robust. For instance, assuming measurements every 15 min, the batteries need only be replaced every 2–4 years (depending on the model/type of the battery). No external part, such as a solar panel, is required to be exposed to the environment. This solution has been implemented in the “Ripple-2” system, developed by the authors (Figure 5) as part of the Soil moisture Sensing Controller And oPtimal Estimator (SoilSCAPE) project.

However, it is not always possible to maintain a low duty cycle. For instance, one could expect to periodically

(and temporarily) modify the schedule of the sensor nodes to make measurements with the full node-density capacity of the network to optimize the scheduling and estimation processes. The main drawback in this case is the high energy cost. By adopting an energy-harvesting model, such as solar panels, one could compensate the additional loss of energy. Accordingly, two additional versions of Ripple-2 node are developed. The Ripple-2B is based on supercapacitors and a solar panel, and the Ripple-2C is a hybrid solution with supercapacitors and non-rechargeable batteries.

The usage of non-rechargeable batteries is not the preferred option for conventional sensor web solutions, in particular for outdoors. The main reason is the high cost involved in frequent battery exchanges (Weddell et al., 2008). Also, typically the energy consumption of the nodes is not uniform among them, and multiple

maintenance trips are necessary. Under the Ripple-2 development, the reasons behind this scenario are investigated, and it is concluded that cooperation among nodes is the main factor for the quick battery depletion. In other words, the average energy spent by a node *serving* the network node is multiple times the energy spent by a node to periodically take measurements and transmit data to the base station (Silva et al., 2012a).

The authors envisioned a scenario where the network is segmented into physical clusters and each segment has a data collector node (LC) that can communicate with all the sensor nodes in that segment by means of a single hop (direct link) (Silva et al., 2012b). By carefully assigning the location of the LC in relation to the sensor nodes of that area, the collaboration among sensor nodes due to multi-hopping is not necessary. As a result, the network overhead is drastically reduced from typical 3–10 % to less than 1 %. Also, a sensor node does not need to periodically wake up to *serve* the network (i.e., relaying messages). Therefore, the sleep scheduling of a Ripple-2 nodes is only governed by the application duty cycle. In other words, the energy consumption of a node has a very deterministic behavior, and energy balance among nodes is finally achieved no matter the size of the network.

Because a Ripple-2 node can potentially have a very long and continuous sleeping period (i.e., hibernation mode), it is possible to turn off many modules, such as the radio transceiver, rather than just put these modules into standby mode. The energy savings achieved by following this approach can be as high as 50 % (Silva et al., 2012a). Combined with the savings related to a reduced network overhead, the lifetime of a non-rechargeable battery of a Ripple-2 node can be realistically extended by multiple folds assuming a low duty-cycle regime, such as soil moisture measurements every 20 min (Menachem and Yamin, 2004).

However, there is an important trade-off in relation to non-rechargeable batteries: the *pulse current effect* which is the nonlinear and drastic energy capacity reduction of a battery when it is discharged by a slight higher current, such as 50 mA (Silva et al., 2012b). No matter how quick is this pulse current (e.g., a very fast radio transmission), the energy capacity of the battery is impacted and its lifetime can be as small as 10 % of the nominal/expected lifetime (Silva et al., 2012a). In order to solve this issue, Ripple-2 adopts supercapacitors as *power-matching* components. That is, these capacitors are slowly charged by a low current from the battery and quickly discharged by a high current (radio). Such approach protects the battery against the pulse current effect but also creates additional data latency issues when the node needs to transmit data very frequently. However, it is not a problem for a low duty-cycle web sensors used in SMAP.

Summary

To respond to the challenge of validation of coarse-scale remote sensing retrieval products such as soil moisture,

a generalized wireless sensor network architecture has been developed. This architecture can be scaled to large-scale outdoor wireless sensor webs with flexible placement, scheduling, and power management schemes. The latest implementation of this architecture has been termed “Ripple-2” (with Ripple-1 being the first generation of this architecture). Due to its advantages, this architecture can be extended not just for soil moisture but for other sensing applications by making it flexible enough for other processor platforms and wireless technologies. Such applications can include any environmental monitoring application that has an extensive network deployed over a large area.

The high degree of robustness, energy efficiency, and reliability of Ripple-2 are achieved under the assumption of low duty cycles (e.g., sensor measurements every 10–20 min) and data latencies from seconds to minutes.

The Ripple-2 architecture can be considered a milestone in wireless sensor networks (WSNs) because of its specialization for low duty cycle and data-centric applications, breaking well-established concepts for WSNs. Without increasing the costs, the energy performance of Ripple-2 nodes is significantly superior compared to any similar WSN/telemetry solution. In fact, even non-rechargeable batteries can now be considered as a cost-effective option. However, technological enhancements can provide the path to turn Ripple-2 into a *generic* WSN solution.

ENVIRONMENTAL TREATIES

Alexander de Sherbinin
Center for International Earth Science Information
Network (CIESIN), Columbia University,
Palisades, NY, USA

Synonyms

Multilateral Environmental Agreements (MEAs)

Definition

Environmental treaty: an environmental treaty is an agreement under international law entered into by two or more states addressing natural resource management or environmental protection. A treaty may also be known as an agreement, protocol, covenant, convention, exchange of letters, accord, exchange of notes, or a memorandum of understanding.

Introduction

Over the past 40 years, there has been a parallel increase in the number, range, and complexity of environmental agreements and the number and sophistication of remote sensing instruments. There were 172 environmental treaties in 1970, and that number has risen to more than 475 today (Mitchell, 2008), covering almost every conceivable environmental system. In terms of civilian or commercial remote sensing instruments, in 1970 there were only a handful of meteorological satellite sensors, whereas today there are more than 100 operational sensors with a wide range of spatial, spectral, and temporal resolutions.

Until the 1990s, the two communities – the international environmental law community, on the one hand, and remote sensing scientists, on the other – largely operated in isolation from one another. True, in the 1980s, images from the Total Ozone Mapping Spectrometer (TOMS) instrument onboard Nimbus-7 were used to document the seasonal depletion of ozone over the Antarctic, a visualization capability that significantly contributed to the Montreal Protocol of the Vienna Convention on Ozone Depleting Substances. But no one had asked the question: What kind of remote sensing data

products are required by the environmental treaty community? In the late 1990s, the two communities began to assess – through a series of workshops and dialogues – the ways in which remote sensing could contribute to international environmental policy making. This entry addresses a number of the opportunities and constraints for the application of remote sensing data to environmental treaties that have been identified through recent dialogues and documented by research projects and publications (cf. CIESIN, 2001; de Sherbinin, 2005; Johnston, 2006; Strand et al., 2007).

Opportunities

One of the greatest attributes of remote sensing is its synoptic view with wall-to-wall coverage. This, coupled with the fact that the data are “objective” and consistent over time, at least compared to the highly variable in situ monitoring between countries and over time, makes remote sensing a potentially ideal source of data for a range of environmental issues of international concern. These include habitat loss, biodiversity conservation, desertification, transboundary air pollution transport, eutrophication of coastal waters, and greenhouse gas emissions from land-based sources, among others. The data are also applicable for regions of widely varying scales, from global down to transboundary resource management contexts.

Another advantage is that, unlike most other data gathering techniques, collection of remote sensing imagery does not infringe national sovereignty. Furthermore, it enables data collection in remote, inaccessible, or war-torn locations at much lower costs than ground-based methods and without risk to personnel.

In terms of treaty processes, remote sensing can be applied in a number of areas. Perhaps the most common use is in the context of environmental assessments. Both the Intergovernmental Panel on Climate Change (IPCC) and the Millennium Ecosystem Assessment relied heavily on remote sensing data to reach science-based conclusions about the scope of climate change and the loss of ecosystem services, respectively. Information from scientific assessments often feed directly into treaty negotiations, leading to new protocols or amendments to treaty texts. Another area of great potential is in national reporting, an often data-intensive process that can be greatly facilitated by remote sensing. For example, in the second national reports of the Convention on Biological Diversity, contracting parties were asked if they were using rapid assessment or remote sensing techniques. Thirteen parties reported a lot of use, 58 reported some use, and 33 reported no use or that they were exploring the possibility.

Perhaps the most important role of remote sensing is its support for the broader political process. Images capture the significance of a problem in a way that the written word does not. Remote sensing before and after images of deforestation or deglaciation has served to bolster public support for stronger environmental agreements

and the national laws that contribute to treaty implementation. Remote sensing has illustrated in powerful ways alterations to a wide range of ecosystems such as the Everglades in the USA, the Aral Sea, and the Amazon basin (UNEP, 2005). These same images can also serve as wake-up calls to political leaders. Political support at the highest levels for the Mesoamerican Biological Corridor, an agreement under the Central American Commission for Environment and Development (CCAD), can be partly attributed to a Landsat image of the Mexico-Guatemala border that portrayed the extent of deforestation in the Mexican state of Chiapas as compared to the neighboring Guatemalan Petén (de Sherbinin et al., 2002).

Traditionally, one of the problems of remote sensing was its high cost. The costs of imagery, software packages, computer processing, and trained technicians were beyond the reach of many developing countries and represented significant barriers even for many developed countries. Fortunately, this is beginning to change. In the case of imagery, costs have come down considerably for all except the highest resolution (1–4 m) commercial imagery. MODIS data are free of charge, Landsat imagery will soon be available at no cost, and data from many other instruments, such as ASTER, are freely available for scientific uses. In addition, there has been a proliferation of instruments with widely ranging characteristics – including radar instruments – that cover a much wider spectrum of the Earth and environmental processes than the few land and meteorological satellites of the 1980s. The growth in availability of imagery with different characteristics has inevitably brought costs down, even for commercial imagery.

The cost of commercial software packages is still fairly high, though a number of shareware packages are now available with some impressive capabilities. The American Museum of Natural History's Biodiversity Informatics web site lists 12 free software packages (AMNH, undated). There are others, such as TerraLook, which prepackages ASTER imagery for use in assessing land cover change in and around protected areas. Although they lack analytical capabilities, web-based applications such as Google Earth and NASA World Wind are popularizing remote sensing imagery in ways that can only enhance their application in the environmental policy realm.

Computer processing power has increased exponentially, and costs have come down in that domain as well. Probably, the only area that has not seen significant cost declines is the salaries for trained technicians. We return to the issue of training in the next section.

In terms of institutional support for the application of remote sensing to environmental treaties, a great stride forward has been made with the establishment of the Group on Earth Observations' (GEO) Global Earth Observation System of Systems (GEOSS). GEOSS is facilitating exactly the kind of dialogue between data users in the environmental policy realm and remote sensing scientists that began in the 1990s, and the dialogue is

now being expanded to Internet technologists who are dreaming up new ways to combine remote sensing imagery with in situ data to better understand and manage the environment.

Constraints

As mentioned in the previous section, a number of former barriers to the use of remote sensing for international environmental policy – such as the high cost of imagery and software – have fallen. Nevertheless, there remain some technical hurdles that may never be fully overcome. One is the basic trade-off between spatial, spectral, and temporal resolution that is governed by basic laws of physics. High-resolution sensors of less than 5 m typically have narrow fields of view with small footprints and long repeat times, making them less useful for broadscale analyses. Though this could be considered a constraint, fortunately most environmental applications do not require such high-resolution imagery.

Another basic fact of life is that the data from passive sensors measure at sensor radiance, not what is actually on the ground. If space-based passive sensors were able to accurately, precisely, and repeatedly capture the actual reflectance from a feature on the ground, regardless of the time of day, season, or weather conditions, much of the hard work of image processing would be eliminated. But the reality is that the atmosphere scatters radiation that is reflected back out to space. Smoke, haze, clouds, and humidity exacerbate the problem and can block reflected energy entirely. This leads to gaps in the archival record. Radar or so-called “active” sensors can see through clouds, but the data are often difficult to interpret given the complicated reflectance patterns of different surface types. Where change detection is needed, there are further problems in discriminating actual on-the-ground changes from apparent changes due to illumination, view angle, or seasonality that affects ground cover.

Another issue is the fact that many remote sensing instruments are experimental, not operational, and this impacts the continuity of the data streams. Many of the most widely used sensors, such as MODIS or SPOT VEGETATION, are from experimental programs and the sensor characteristics will not be replicated in future missions. Even some operational sensors such as Landsat, which was until recently the most widely used sensor for environmental applications, have had data gaps due to technical failures and delays in planning continuity missions.

Beyond the constantly varying data streams, as new experimental sensors come online or older sensors fail, standard algorithms for many environmental applications have yet to be developed. The conclusion of one survey of remote sensing methods applied to biodiversity assessment and conservation found that there is great promise for their application, especially as new remote sensing instruments become available but that the field lacks a set of standard methodologies that could move

remote sensing applications from an experimental to an operational stage of implementation (de Sherbinin, 2005). In the realm of international law, replicability of observations and the reliability and consistency of measurements are of paramount importance (GOFC-GOLD, 2012). Algorithms also need to be validated through field studies or “ground truthing” that can be many times more expensive than the initial image processing.

As mentioned in the previous section, training is still somewhat of a barrier to wider application of remote sensing in the treaty realm, and this affects two communities. The first is the science community, which needs to ensure that adequate training programs are developed at undergraduate and graduate levels that ensure that students are grounded in the basic science behind remote sensing so that scientific findings are robust. The second is the policy community. Without a basic literacy in the science behind remote sensing, many contracting parties and treaty secretariats lack the ability to critically evaluate scientific findings. This results in either the uncritical acceptance of findings which may in fact be wrong (which is probably the more likely scenario) or the discounting or rejection of findings because of a lack of understanding of what the imagery tells us. This suggests that there is a need for increased literacy among the policy community concerning the science upon which remote sensing is based so as to make informed decisions.

On the policy side, there are other constraints. One of the areas which remote sensing scientists have been keenest in promoting is the potential for remote sensing to be used for treaty monitoring and enforcement. Although the remote sensing does hold out the promise of more rigorous regimes based on real monitoring, the reality is more complex. Because most environmental treaties are considered “soft law” based on consensus approaches to environmental management, treaty secretariats and Parties have typically shied away from even suggesting the use of remote sensing in a compliance context. Until more environmental treaties are crafted in such a way as to have enforceable requirements, the full promise of monitoring and enforcement applications will not be met.

Still, there have been research projects exploring the potential of remote sensing for compliance enforcement among the few agreements with requirements. One was in the case of the Bonn Agreement, officially known as The Agreement for Cooperation in Dealing with Pollution of the North Sea by Oil and Other Harmful Substances (1983). In that case, researchers were exploring the use of SAR images to detect oil slicks on the high seas (Jones, 2001). It was found that SAR gave an unacceptably high level of false-positives, and even if it could identify oil slicks, establishing the connection between a slick and a vessel would need to be corroborated by photographic evidence according to the terms of the convention. Another research project in Bolivia sought to apply a combination of ground-based measurements and aerial

videography to afforestation, reforestation, and deforestation (ARD) monitoring in the context of the Kyoto Protocol (see Noel Kempff Mercado Climate Action Project). Ultimately, to be applicable at broader scales, ARD monitoring will require a wider array of satellite sensors (including LIDAR) and more automated techniques than are currently available (Rosenqvist et al., 1999; CIESIN, 2001; GOFC-GOLD, 2012).

Other policy constraints include a lack of expertise on the part of treaty secretariats to assimilate remote sensing imagery or its results in their standard practices, and a fear by some, particularly developing country parties, of a “big brother” approach to compliance monitoring. Related to the former, it could be said that until recently there was a “technology push” on the part of space agencies and scientists rather than a genuine acceptance of remote sensing in the treaty world, lending the appearance of data developers in search of applications. An example was the European Space Agency’s Treaty Enforcement Services using Earth Observation (TESEO) project, later subsumed under the Data User Element for MEAs. This technology push, however, was not necessarily a bad thing. TESEO was successful in engaging a number of treaty secretariats such as that of the Ramsar Convention on Wetlands and the Convention to Combat Desertification (CCD) and informing their staff. One impact metric is that references to remote sensing or satellite imagery in Ramsar Conference of Party (COP) decision documents increased from no references in all up until 1999 and then three references at COP7 (1999), three references at COP8 (2002), and four references at COP9 (2005). In the case of UNCCD, there were no references to either term until COP8 (2007) (SEDAC, 2010).

For its part, the US National Aeronautics and Space Administration (NASA) engaged the Convention on Biological Diversity (CBD) secretariat as well as a number of partners through its NASA-NGO Biodiversity Working Group. Working with the CBD and the World Conservation Monitoring Centre, the working group published the *Sourcebook on Remote Sensing and Biodiversity Indicators* (Strand et al., 2007), which provides a good balance of technical and applied information concerning the application of remote sensing that is useful to the CBD community.

Conclusion

In conclusion, although a number of technical and political obstacles remain, in all likelihood remote sensing will play an increasing role in international environmental politics, including in the treaty realm. Treaty-specific applications are likely to be enhanced as treaty secretariats or those familiar with treaty provisions actually participate in instrument design teams. The GEOSS 10 year action plan, established in 2005, makes reference to a number of application areas that are central to environmental treaties such as the UN Framework Convention on Climate Change, the CBD, the CCD, and Ramsar, including:

- Improving management of energy resources
- Understanding, assessing, predicting, mitigating, and adapting to climate variability and change
- Improving water resource management through better understanding of the water cycle
- Improving the management and protection of terrestrial, coastal, and marine ecosystems
- Supporting sustainable agriculture and combating desertification
- Understanding, monitoring, and conserving biodiversity

The document specifically states that GEOSS will “further the implementation of international environmental treaty obligations.” An early workshop for the GEO Biodiversity Observation Network (Potsdam, Germany, April 2008) included significant representation of remote sensing scientists, and treaty secretariats have been engaged in the Network’s development.

Although remote sensing is not a panacea for the data and information needs of environmental treaties, and though even the best data does not guarantee action on the growing list of environmental problems, the data do represent a significant resource that will undoubtedly contribute to environmental assessments and serve to strengthen treaty mechanisms well into the future.

Definition

Remote sensing is the technique to retrieve information about an object without being in physical contact with it (Elachi, 1987). This information is acquired by detecting and measuring changes that the object under investigation imposes on the surrounding field.

The interacting field can be an electromagnetic, acoustic, or gravitational field. The *electromagnetic field* is due to space–time variations of the electric and the magnetic fields (Ulaby et al., 1981; Ishimaru, 1991). Static electric and magnetic fields can be originated by a stationary electric charge distribution or by stationary currents or ferromagnetic materials, respectively. The electromagnetic methods, which are the most frequently used in remote sensing, cover the whole electromagnetic spectrum from radio-frequency waves to gamma rays through microwaves, submillimeter waves, and far infrared, near infrared, visible, ultraviolet, and x-ray waves. *Acoustic fields* are due to the continuous exchange between the fluid kinetic energy and the potential energy store during fluid compression (Lighthill, 1978). The acoustic refraction of Earth atmosphere depends on temperature, wind, and, to a lesser extent, on humidity. *Gravitational fields* are due to gravitational forces, typically exerted by a planetary mass. The gravitational fields determine the dynamics of objects embedded in the field itself.

Radiation represents the field propagation through waves. Amplitude, phase, polarization, and power are typical features of a field radiation (Elachi, 1987). The latter

can be generated by transformation of energy from other sources such as kinetic, chemical, thermal, electrical, magnetic, or nuclear. Several transformation mechanisms can lead to field waves over different regions of the frequency spectrum. Generally speaking, the more organized the transformation mechanism is, the more coherent is the generated radiation. From a theoretical point of view, radiation can be stated through the wave equation which describes the wave propagation phenomenon for electromagnetic, acoustic, and gravitational fields (Ishimaru, 1991). Physical properties of the media where the field is generated, such as temperature, humidity, shape, and composition, determine the medium properties which govern the field–matter interaction. The refractive index of the atmosphere is a typical example of electric properties which influence electromagnetic propagation.

Due to their inherent remote operation, remote sensing systems must exploit a *propagation mechanism*. The capability to infer the characteristics of the object under remote observation are derived from the properties of the wave field that has interacted, through emission, absorption, scattering, reflection, or transmission, with the object itself (Ishimaru, 1981). The retrieved field interactions are mainly due to reflection, scattering, and transmission in case of active remote sensing systems, whereas to absorption and emission in case of passive systems. The reflected or scattered radiation has generally the same frequency of the incident one; however, there exist processes which can produce irradiation at frequencies different from the incident wave one, such as Raman scattering and fluorescence, in case of electromagnetic waves. Transmission properties of media determine the capability of radiation to penetrate the medium itself.

FISHERIES

Cara Wilson
 Southwest Fisheries Science Center, NOAA/NMFS,
 Environmental Research Division, Pacific Grove,
 CA, USA

Definition

Catch per unit effort. CPUE standardizes fish catch data based on the amount of the effort (total time or area sampled) exerted.

Fishery stock. A subpopulation of a particular species in a given area. Unlike a fish population, a stock is defined as much by management concerns (such as jurisdictional boundaries or harvesting location) as by biology. There are three different types of stocks: commercial (exploited) species, unexploited species, and protected species. Stocks are not restricted to just fish, but also include marine mammals and invertebrates.

Fisheries stock assessment. An estimate of either the total population or total biomass of a fisheries stock. Stock assessments are a crucial component of fisheries management.

Fisheries management. The protection and management of fishery stocks to maintain sustainable exploitation for commercial species, and to recover the populations of protected and endangered species.

Fisheries oceanography. The study of oceanic processes affecting marine ecosystems and the relationship of these ecosystems to the abundance and availability of fish (Harrison and Parsons, 2001).

Living marine resources (LMR). A term to refer to all types of stocks, which is not restricted to just fish, but also includes marine mammals and invertebrates.

Operational fisheries. Utilizing oceanographic information to maximize the efficiency of fishing efforts.

Recruitment. The amount of fish added to the stock each year due to reproduction and/or migration into the stock area.

Fisheries and remote sensing

Introduction

In the broadest sense, fisheries encompass not just commercial fish stocks, but all living marine resources (LMRs), which for threatened and endangered species involve efforts to help the populations recover. There are three distinct aspects of fisheries: harvesting, assessment, and management, all of which have different goals. Harvesting efforts focus on increasing the catch per unit effort (CPUE), that is methods of finding, and more efficiently catching, more fish. Assessment involves both the species and its habitat. Stock assessments estimate either the total population or the total biomass of a fisheries stock in a given region, whereas habitat assessments characterize the environmental conditions favored by a species. Fisheries management uses both stock assessments and habitat assessments to set harvesting limits and guidelines on commercial stocks to maintain sustainable exploitation, and also to develop regulations to help recover the populations of protected and endangered species.

In the last half century, the world fish harvest has increased more than fourfold from 20 million tons in 1950 to over 90 million tons in 2000 (FAO Fisheries Department, 2004). At the same time the number of overexploited and depleted stocks has increased, and an expanding human population and problems with food supply have increased the pressure on fisheries resources. Better management and understanding of fisheries are needed to both maximize the utility of the current resources, and to ensure their sustainability into the future. However, these issues are complicated by the significant interannual variations that occur in fish populations, and sorting out fluctuations caused by anthropogenic effects (overexploitation, habitat alteration, pollution, etc.) from those caused by natural environmental variability is not trivial. The fundamental question of what drives the interannual variability of fish stocks was first posed over 100 years ago with the formation of the International Council for the Exploration of the Seas (ICES) in 1902, and still has not been adequately resolved (Kendall and Duker, 1998; Bakun and Broad, 2003).

Satellite data provide an environmental context within which to examine these issues, by measuring parameters of the habitat and ecosystems that influence marine resources at high temporal and spatial scales. There are two primary ways that satellite data are used within fisheries. One is to find populations, usually a commercial fish stock to increase CPUE, but also in some cases for conservation, for example, trying to identify locations of endangered cetaceans in order to minimize the number of lethal interactions with ships. A second application is characterizing and monitoring the habitat that influences living marine resources (LMRs). Most of the dynamic features that are important to ecosystems, that is, oceanfronts, eddies, convergence zones, river plumes, and coastal regions, cannot be adequately resolved without satellite data. Similarly,

Fisheries, Figure 1 Schematic representation of the ocean food web.

satellite data are crucial for resolving the timing of processes such as upwelling, harmful algal blooms, seasonal transitions, and El Niño events. Remotely sensed variables such as sea surface temperature (SST), sea surface height, ocean color, ocean winds, and sea ice are all used to characterize relevant environmental conditions (SSH, ocean color, ocean winds and sea ice, here and elsewhere). Additionally, environmental satellite data are used to monitor a number of issues that impact fisheries, such as coastal pollution and coral reef bleaching events. For some coastal applications, particularly aquaculture, high-resolution imagery data has been a useful tool. Many of these applications are described in more detail in the IOCCG's (International Ocean Colour Coordinating Group) report on remote sensing in fisheries and aquaculture (IOCCG, 2009) and in the proceedings of an international symposium on remote sensing and fisheries held in 2010 (Stuart et al., 2011).

Satellite ocean color is particularly important to fisheries, since it is the only remotely sensed parameter that directly measures a biological component of the ecosystem (Wilson et al., 2008). Satellite chlorophyll provides an index of phytoplankton biomass, which is the base of the oceanic food chain, or food web, as depicted in simplified form in Figure 1. The relationship between satellite chlorophyll data and a specific fish stock depends upon the number of linkages between phytoplankton and the higher trophic level. For some species, such as anchovies and sardines, which eat phytoplankton at some points in their life cycle, the linkage can be direct (Ware and Thomson, 2005), whereas for other species there are many trophic levels in between and the relationship can be nonlinear. There can also be spatial disconnects between satellite measurements of the ocean surface and demersal

and deepwater species. Nonetheless, chlorophyll is the only biological component of the marine ecosystem accessible to remote sensing, and as such it provides a key metric to measuring ecosystems on a global scale. Satellite chlorophyll measurements are the primary component in algorithms to calculate the primary productivity (PP) of the ocean. Global PP measurements, in conjunction with fish catch statistics and food web models, such as shown in Figure 2, can be used to estimate the carrying capacity of the world's fisheries. In the open ocean 2 % of the PP is needed to support the fishery catch, but in coastal regions the requirement ranges from 24 % to 35 %, suggesting that these systems are at or beyond their carrying capacity (Pauly and Christensen, 1995), which is a cause for concern as the bulk of the world's fish catch comes from coastal areas. In a similar manner, discrepancies between the values of satellite-derived PP and reported fish catches have been used to demonstrate spurious trends in global fish catches as reported by the Food and Agriculture Organization (FAO) of the United Nations (Watson and Pauly, 2001). In this instance satellite ocean color data provide an important objective baseline against which to gauge data that can have socioeconomic biases.

Operational fisheries (harvesting)

Locating and catching fish is becoming more challenging as fish stocks dwindle and move further offshore, thus increasing the search time, cost, and effort. Satellite data can help to increase CPUE by identifying oceanographic features that are often the sites of fish stock congregation and migration such as temperature fronts, meanders,

Fisheries, Figure 2 Cartoon of the connection between satellite measurements to fisheries through measurements of chlorophyll-bearing phytoplankton.

eddies, rings, and upwelling areas (Laurs et al., 1984; Fiedler and Bernard, 1987; Chen et al., 2005). Assuming adequate catch limitations are in place, increasing the CPUE is not incompatible with maintaining a sustainable fish stock population.

Both satellite ocean color and SST data have been used for increasing fishing efficiency. SST and ocean color often have similar patterns as generally warm, nutrient-depleted water has low chlorophyll concentrations and cold, nutrient-rich water has high chlorophyll. SST can also be an important factor for determining potential fishing grounds since different fish species have different optimal temperature ranges. Generally SST data have been used more often than ocean color data in fisheries applications. There are two main reasons for this. One, satellite SST is a more established data source, with data going back to 1981, whereas SeaWiFS, the first satellite to consistently provide satellite chlorophyll data on a global basis, was not launched until 1997. Second, SeaWiFS was a privately owned satellite, and while its data was always freely available, with a time delay, to the research community, the availability of near real-time (NRT) data needed by fishers for identifying potential fishing areas was only available on a commercial basis. For economic reasons that resulted in SeaWiFS data being unavailable to many fishers in the world, as the commercial costs of the real-time data can be prohibitive, particularly for those in underdeveloped countries, which is

where 70 % of the fish for human consumption comes from (FAO Fisheries Department, 2004). Ocean color data from the MODIS instrument on Aqua, launched in 2002, is available at no cost on an NRT basis.

For use in increasing the CPUE, satellite data must be available in a near real-time basis. There are international differences in how satellite data are disseminated to fishers, as national agencies serve different constituencies (Wilson, 2011). The mandate of NOAA Fisheries in the USA, for example, is to manage and conserve marine resources, and they are not allowed to provide services such as distributing “fish finding maps” that would compete with commercial interests. However in other countries, notably Japan and India, the national fisheries agencies are actively involved with helping increase the efficiency of their fishing fleets. For example, data from the Indian Ocean color satellite (in conjunction with satellite SST) are used by the Indian National Center for Ocean Information Services (INCOIS) to make maps of potential fishing zones (PFZ), which are freely disseminated several times a week throughout coastal India by fax, phone, Internet, electronic display boards, newspaper, and radio broadcasts. Studies on the effectiveness of the PFZ advisories have suggested that they have helped reduce search time by up to 70 % and have significantly increased the CPUE (Solanki et al., 2003; Zainuddin et al., 2004).

Stock assessment

While satellite remotely sensed data are now widely used in operational fisheries, their use in stock assessments is just beginning (Koeller et al., 2009). The incorporation of environmental data of any kind into stock assessment models has rarely been achieved successfully, for several reasons. Assessments have traditionally taken classical single species approaches which deal only with the numeric population dynamics of the stock under review – the fish stock as “bank account,” with principal (abundance), interest (growth), deposits (recruitment), and withdrawals (natural and fishing mortality) determined by research vessel surveys and fishery (catch, effort) data. The environmental factors forcing change to the bank account are complex, poorly understood, and difficult to measure; consequently, they have largely been excluded from traditional assessment models, greatly limiting their accuracy and effectiveness (Koeller et al., 2009). Additionally, radical changes to methodology, such as incorporating environmental data, would compromise the interannual time series of a stock population derived from stock assessments.

However, the advent of the “ecosystem approach to fisheries” (EAF) has given new impetus to better understand the environmental factors influencing fish stock dynamics and to try to include environmental variability as an integral part of the assessment process. It is particularly important to develop an understanding of the factors determining recruitment of commercially important fish and

shellfish stocks, for two reasons: first, the adverse effects of fishing cannot be separated from “normal” environmentally driven changes unless the latter are thoroughly understood. Second, environmental factors modify underlying stock-recruitment relationships, arguably the most important information necessary to define reference points and achieve fisheries sustainability. Until recently, defining stock-recruitment relationships and identifying the environmental factors modifying them have been the “holy grail” of fisheries research, largely unresolvable with traditional oceanographic methods because of the complex, large- and small-scale spatial/long- and short-term temporal processes involved. However, the availability of environmental satellite data such as ocean color, SST, and altimetry is now making these objectives achievable.

Recruitment

A fundamental issue in fisheries oceanography is understanding how environmental variability affects annual recruitment, the number of new individuals entering a stock. Recruitment is an important parameter because the bulk of mortality occurs in the development of larvae from eggs. Most fish have planktonic larval stages that are strongly influenced by ocean circulation and can have narrow ranges of optimal thermal conditions. Availability of a good food source is important for successful recruitment and hence many fish reproduce near the seasonal peak in phytoplankton abundance. A long-standing hypothesis in fisheries has been that recruitment success is tied to the degree of timing between spawning and the seasonal phytoplankton bloom, the Cushing-Hjort or match-mismatch hypothesis (Cushing, 1969, 1990). This hypothesis has been difficult to address with traditional shipboard measurements that have limited spatial and temporal resolution, but with satellite ocean color data, interannual fluctuations in the timing and extent of the seasonal bloom can be clearly seen. In an application on the Nova Scotia Shelf, the timing of the spring bloom determined from satellite ocean color was compared with available in situ data on larval survival of haddock, an important commercial fish species. Comparison of these two independent data sets indicated that highly successful year classes of haddock are associated with exceptionally early spring blooms of phytoplankton, confirming the match-mismatch hypothesis (Platt et al., 2003). A comparable study has also documented a relationship between the timing of the spring bloom and the growth rate of shrimp (Fuentes-Yaco et al., 2007). These studies demonstrate that it can be possible to separate ecosystem-associated variability in fish stocks from other components such as human exploitation or predation effects. The satellite time series permits the extraction of value-added products, in this case the timing of the seasonal biological cycle. Understanding these processes will lead to improved and longer term fisheries forecasts, that is, for the period between birth and capture, which for some species can be as much as a decade.

Habitat assessment

Coral reef monitoring

Coral reef ecosystems support a high diversity of coral, fish, and benthic species, with corals forming the structural and ecological foundation of the reef system. Coral reefs are sensitive to their environment (temperature, light, water quality, and hydrodynamics), and as a result of both anthropogenic and climate impacts (Kleypas et al., 2001), they are among the most threatened coastal ecosystems worldwide (Pandolfi et al., 2003; Hoegh-Guldberg et al., 2007). Corals have a symbiotic relationship with a microscopic organism, zooxanthellae, which provides the corals with oxygen and a portion of the organic compounds they produce through photosynthesis. When stressed, many reef inhabitants expel their zooxanthellae en masse. The polyps of the coral are left bereft of pigmentation and appear nearly transparent on the animal's white skeleton, a phenomenon referred to as coral bleaching.

Severe bleaching events can have dramatic long-term effects on the coral. Recovery rates appear to differ with species, and the time required to attain full recovery of symbiotic algae varies from as little as 2 months to as much as 1 year. When the level of environmental stress is high and sustained, the coral may die. Since the late 1980s, coral bleaching related to thermal stress has become more frequent and more severe. High SSTs associated with the 1997–1998 El Niño caused bleaching in much of the world's oceans, particularly in the Indian Ocean and in the western Pacific. Other major bleaching events occurred around the Great Barrier Reef and Northwestern Hawaiian Islands in 2002 and in the Caribbean in 2005.

With the capability of providing synoptic views of the global oceans in near real time and the ability to monitor remote reef areas, satellite remote sensing has become a key tool for coral reef managers and scientists (Mumby et al., 2004; Maina et al., 2008; Maynard et al., 2008). Since 1997, NOAA has been producing near-real-time, web-accessible, satellite-derived SST products to globally monitor conditions that might trigger coral bleaching from thermal stress. Currently NOAA's Coral Reef Watch Program provides operational products such as SST anomalies, bleaching hot spot anomalies, Degree Heating Weeks, and Tropical Ocean Coral Bleaching Indices to the global coral reef community (Strong et al., 2006). These products provide an effective early warning system globally, but are not always accurate in predicting the severity of a bleaching event at a regional scale (McClanahan et al., 2007; Maynard et al., 2008). In Australia, CSIRO's (Commonwealth Scientific and Industrial Research Organisation) ReefTemp project produces satellite-derived bleaching risk indices specifically for the Great Barrier Reef (Maynard et al., 2008).

Tagging

Electronic tagging of LMRs is a key methodology to gather information needed for accurate and responsible fisheries management. Satellite data is crucial to place

track data in an environmental context, in order to fully understand foraging and migration patterns, fish behavior and feeding ecology, habitat selection, and individual and population-level responses to environmental and climate variability. This approach has been used to characterize the environment of a wide variety of tagged species – turtles, penguins, seals, salmon, etc. – to better understand both their behavior and their habitat (Block et al., 2003; Hinke et al., 2005; Ream et al., 2005; Polovina et al., 2006; Weng et al., 2007). An example of this is described in fuller detail under the “Sea Turtles” subheading in the “Management of Protected Species” section.

Survey support

Fishery independent surveys are a crucial part of stock assessment. Just as satellite data can be used to increase fishing CPUE by identifying front locations and other features where fish tend to congregate, these data are also routinely used by fisheries cruises doing survey assessments for management and stock assessment. The near real-time data are valuable for locating fronts and other relevant features to sample across, as well as placing the results in a larger spatial context.

Fisheries management

Vessel monitoring system (VMS)

A standard fishery management tool is to close certain areas to fishing or to establish restricted fishing in certain areas, but ensuring that regulations and laws are being adhered to can be difficult for enforcement agencies. Satellite-based vessel monitoring systems (VMS) enable vast expanses of the ocean to be effectively monitored. By using a transmitter aboard commercial fishing vessels, paired with traditional global positioning satellites, vessels can be monitored while at sea to determine if they are fishing in closed areas or out of season. An obvious limitation of VMS is that vessels without installed VMS units, or vessels with faulty VMS units, are not monitored. In many fisheries, fishing vessels are required to carry an operational VMS transmitter, but illegal fishing is still possible by noncompliant fishing vessels. Recently synthetic aperture radar data have been used to successfully identify noncompliant fishing vessels, that is, vessels operating without VMS units (Kourti et al., 2005). In addition to their aid in enforcement of fisheries regulations, VMS data can provide valuable information to managers about both fish stock distributions and patterns of fishing activities (Deng et al., 2005; Mills et al., 2007; Bertrand et al., 2008).

Management of protected species

Monk seals

In the late 1980s, field programs monitoring monk seal pup survival, sea bird reproductive rates, and reef fish densities in the Northwestern Hawaiian Islands (NWHI) indicated ecosystem changes had occurred.

However, due to a lack of oceanographic data at sufficient space and time scales, it was difficult to construct environmental indicators, or envision how environmental variation might be coupled with the higher trophic level changes (Polovina et al., 1994). The launch of the SeaWiFS ocean color sensor in 1997 allowed assessment of basin-wide biological variability across the Pacific. The SeaWiFS imagery shows that during the winter, the northern atolls of the Hawaiian Archipelago, Kure, Midway, and Laysan Atolls are located at the boundary between the cool, high surface chlorophyll, vertically mixed water on the north and the warm, low surface chlorophyll, vertically stratified subtropical water on the south. This boundary has been termed the transition zone chlorophyll front (TZCF) (Polovina et al., 2001).

In some years, the TZCF remains north of these northern atolls throughout the year, while in other years, the TZCF shifts far enough south during the winter to encompass these atolls with higher chlorophyll water. Hence, the ecosystem of the northern atolls is more productive after the TZCF is located more southerly relative to its long-term winter position. Specifically during a winter when the TZCF was shifted south of its average position, monk seal pup survival increased 2 years later (Baker et al., 2007). The 2 year time lag probably represents the time needed for enhanced primary productivity to propagate up the food web to monk seal pup prey. Should management action, such as a head start program, be developed to improve pup survival, a 2 year forecast based on satellite ocean color can be used to predict the years when low survival is likely and hence when management intervention is needed.

Right whales

With fewer than 400 individuals left, the North Atlantic right whale is one of the most endangered whale populations (International Whaling Commission, 1998; Kraus et al., 2005). This population spends much of its time in US and Canadian waters, with the winter calving grounds off of Florida, Georgia, and South Carolina, and feeding grounds in the Gulf of Maine. The recovery of this population is limited by high mortality, especially due to ship strikes and entanglements in fishing gear. Because its habitat overlaps with lucrative fishing grounds and shipping lanes of major US ports, reducing mortality is politically and economically challenging (International Whaling Commission, 1998; Kraus et al., 2005). The current management strategy involves limiting adverse impacts by requiring modifications to fishing gear or vessel speeds in regions and time periods when whales are likely to be present. Thus, all management options require knowing when and where whales are likely to be. The question is how to identify these likely regions within a dynamic ocean environment.

A new approach to locating right whales combines synoptic information from satellites with a model of the right whales' main prey. Right whales feed on small crustaceans

called copepods, especially the large and abundant species *Calanus finmarchicus*. High numbers of whales are typically found in regions of high copepod concentrations (Pendleton et al., 2009). Many important rates in *Calanus*'s life cycle can be estimated using satellite data. The time required for an egg to develop into an adult is related to temperature, with shorter generation times in warmer water. Using satellite chlorophyll as a proxy for phytoplankton, the main food of *Calanus*, determines how quickly a female copepod can produce eggs. By combining the rate information derived from satellite data with reconstructions of the ocean currents from a computer model, estimated maps of *Calanus* abundance can be produced and related to right whale distributions (Pershing et al., 2009a, b). An initial test of this system forecasted that due to the cold winter in 2008, the *Calanus* population would be delayed, and that whales would arrive on their main spring feeding ground east of Cape Cod 3 weeks later than normal. While a full analysis of the data is underway, it appears that the whales arrived close to when the model predicted. These forecasts are currently being expanded to include a wider area of space and time and will soon be able to incorporate observations of both copepods and whales.

Sea turtles

A pelagic longline fishery based in Hawaii occasionally catches several species of sea turtles, with the threatened loggerhead sea turtle historically accounting for the majority of the turtle bycatch. Since 1997, Argos-linked transmitters have been attached to loggerhead sea turtles caught and released by longline vessels (Polovina et al., 2000), in order to characterize migration and forage areas of loggerheads, with the aim of spatially separating the fishery from the loggerheads. In recent years, the number of tracked turtles has been augmented by releasing hatchery reared loggerheads provided by the Port of Nagoya Aquarium, Nagoya, Japan. To characterize turtle habitat it is necessary to place their tracks within an environmental context. The use of satellite SST, ocean color, altimetry, and wind data have all been important in defining the oceanographic habitat of turtles within the North Pacific (Polovina et al., 2000, 2004, 2006; Kobayashi et al., 2008), allowing determination of seasonal habitat maps (Kobayashi et al., 2008). By combining this information with fisheries and fisheries bycatch data, it is now possible to predict the locations of areas with a high probability of loggerhead and longline interactions (Howell et al., 2008). In 2006, NOAA launched an experimental product called TurtleWatch, which uses satellite oceanographic data to map, in near real time, areas with a high probability of loggerhead and longline interactions, so that fishers can avoid them. This information benefits both the turtles and the fishers, who operate under strict limits on the number of turtle interactions allowed. The TurtleWatch tool is generated and distributed daily in near real time since the zone with the high probability of loggerhead bycatch is

a temporally dynamic feature. The TurtleWatch product is also provided to fishers onboard via a commercial fisheries information system.

Aquaculture

Many aquaculture species (e.g., bivalves, shrimp) are suspension feeders and derive nutrition from particulates, the most nutritious being phytoplankton. Bivalve aquaculture can have a significant impact on the local environment by reducing both the levels of particulates in the water, and of anthropogenic eutrophication (Lindahl et al., 2005). Given its ability to measure both phytoplankton and also turbidity (Hoepffner et al., 2008), which is detrimental for some species, satellite ocean color data can be a valuable tool in aquaculture development, but currently it is underutilized in this capacity (Grant et al., 2009). The primary reason for this underutilization is resolution – many aquaculture sites are below the spatial detection of single pixels, for example, small estuaries and bays 1 km wide (see *Coastal Ecosystems*). Various high-resolution commercial satellites have been used for aquaculture applications such as mapping mussel farms (Alexandridis et al., 2008), and site selection for nearshore aquaculture sites has been routinely based on the use of multispectral images from high spatial-resolution sensors (e.g., Landsat, Spot) which more recently have been complemented with the application of sensors such as Aster or IRS LISS/PAN (Dwivedi and Kandrika, 2005). However, medium resolution environmental satellite data can be used for open ocean applications. For example, site selection of sea bream and sea bass cages near the Canary Islands (Spain) made extensive use of SST data for the identification of suitable culture temperatures in the region (Pérez et al., 2003). Radar imagery (ERS-2 and RADARSAT) has been used to inventory and monitor milkfish cage culture in the Philippines (Travaglia et al., 2004).

Fisheries and climate

The SeaWiFS ocean color sensor was launched in August of 1997, just prior to the 1997/1998 El Niño which was one of the strongest ENSO (El Niño-Southern Oscillation) events of the century. This satellite data, in synergy with data from an extensive array of moorings across the equatorial Pacific, has contributed enormously to our understanding of ENSO dynamics and their ecosystem impacts. Deepening of the thermocline, and cessation of upwelling along the equator and in the coastal ecosystems, lowers ocean productivity and causes significant drops in the anchovy fisheries of Peru and Chile (Alamo and Bouchon, 1987; Escibano et al., 2004). However, other species are positively impacted by El Niño, for example, increases are observed in the biomass of sardine and mackerel (Bakun and Broad, 2003; Niquen and Bouchon, 2004). Satellite ocean color data have demonstrated that the effects of El Niño are not constrained to just the equatorial and coastal upwelling regions, but extend throughout most of the Pacific Ocean. For example,

during the 1997/1998 event the TZCF was shifted $\sim 5^\circ$ south of its regular position (Bograd et al., 2004), and lower chlorophyll values occurred across most of the subtropical Pacific (Wilson and Adamec, 2001).

Since we only have continuous ocean color data from 1997 onward, it is not possible to detect decade-scale variability with just these data (see *Climate Monitoring and Prediction*). However, it is possible to observe long-term changes by comparing climatological SeaWiFS data with data from the Coastal Zone Color Scanner (CZCS), which operated between 1979 and 1985. For example, the present wintertime position of the TZCF in the Pacific is about 5° further north than it was during CZCS time period, and this shift has also been seen in SST data used as a proxy for the TZCF (Bograd et al., 2004). Data from these two different satellites have also been used to demonstrate regions of the ocean which have experienced significant changes in the amount of chlorophyll and primary productivity in the past 20 years (Gregg and Conkright, 2002; Gregg et al., 2003).

There is significant long-term temporal variability in fish stocks, and for over 150 years, scientists have been trying to differentiate the effects of interannual variability, overfishing, and long-term changes such as regime shifts, which are characterized by relatively rapid changes in the baseline abundances of both exploited and unexploited species (Polovina, 2005). Long-term variations in ecosystems often follow trends or patterns also observed in ocean and atmosphere parameters (Mantua et al., 1997; Hare, and Mantua, 2000; Peterson and Schwing, 2003). For example, a shift in the North Pacific in the 1970s between a shrimp-dominated ecosystem to one populated primarily by several species of bottom-dwelling groundfish species coincided with a regional change from a cool to a warm climate (Botsford et al., 1997; Anderson and Piatt, 1999). While similar phenomena have been seen for many different stocks, and in all ocean basins, the mechanisms that link large-scale ocean and atmosphere dynamics to changes in population abundances are not always clear (Botsford et al., 1997; Baumann, 1998) and the relationships are not always constant over time (Solow, 2002). Ecosystem changes related to regime shifts are not in themselves harmful to the ecosystems as a whole (Bakun and Broad, 2003), but in order to maintain sustainability, management practices must be flexible enough to recognize and accommodate them (Polovina, 2005). One of the current limitations of satellite data is their relatively short time-spans. For fisheries applications it is crucial that climate quality records of ocean color be maintained so that existing satellite records will be able to serve as a benchmark against which to gauge future changes and to track historical variations.

Summary

Satellite data characterize oceanic properties of habitat and ecosystems that influence living marine resources at spatial and temporal resolutions that are impossible to achieve any other way. The high spatial resolution

provides an important geographical context for interpreting other data. The daily-to-weekly temporal resolution allows for effective monitoring of many oceanic features and permits the extraction of value-added products such as the timing of seasonal events. For fisheries applications it is crucial that climate quality records of ocean color be maintained so that existing satellite records will be able to serve as a benchmark against which to gauge future changes and to track historical variations. These time series of science-quality satellite data are needed to understand linkages between climate and ecosystems, and to characterize and monitor ecosystems as part of an ecosystem-based approach to fisheries management.

Definition

Forestry. The science of planting, monitoring, describing, and managing forests and forest systems and tree plantations for their goods and services, often for commercial production, natural resource use, and habitat preservation. More recently, consideration of the role of forests in carbon cycling and cultural and spiritual values is included.

Introduction

Remote sensing has a long history in forestry, starting with the use of aerial photography in the early 1900s and progressing to more advanced satellite and airborne sensors today. While photointerpretation of aerial photography remains an important tool (Wulder, 1998), the launch of Landsat in 1972, and proliferation of numerous digital airborne and spaceborne sensors since then have broadened the types of research questions that can be asked, and the spatial area over which forests can be mapped and monitored.

The wavelength-dependent intensity of electromagnetic radiation reflected or emitted from vegetation is a product of light scattering and absorption processes occurring at multiple scales. At the finest scales at or below the scale of an individual leaf or branch, the interaction varies depending on anatomy (i.e., thickness, internal structure, optical discontinuities between cell membranes) and biochemistry (molecular absorptions due to water, pigments, and other biochemical compounds and chlorophyll fluorescence; Gates et al., 1965). At canopy scales, the interaction depends upon the number of scatterers and absorbers and their physical arrangement, such as the number of leaves per unit volume and their angular distributions, the ratio of leaves to branches, crown geometry, and tree height. At stand scales, important stand attributes include tree density (trees/unit area), species composition, and stand area. In the reflected solar spectrum (0.350–2.5 μm), the manner in which these

multiscale processes modify reflected light can be used to infer important plant biochemical or structural properties, such as the number of leaves per unit ground area, known as Leaf Area Index (LAI: Figure 1). Biochemical, anatomical, and structural differences can also be used to discriminate tree species (Figure 2), map invasive tree species or forest pathogens (Wulder et al., 2006), and infer species diversity (Asner et al., 2009). In the Mid- and Thermal infrared (IR: 2.5–14 μm), emission depends on the temperature of individual canopy components (leaves and branches) and wavelength-dependent emission efficiency, called emissivity (Salisbury and Milton, 1988). Emissivity is very high for water-filled leaves and lower for branches and stems. Given knowledge of emissivity, canopy temperatures can be estimated and used to infer important plant physiological processes, such as rates of evapotranspiration. In the microwave (>1 mm), scattering and absorption depend on the physical size of canopy components, their orientation, and their dielectric properties, which are largely controlled by water content. Large, water-filled branches are highly reflective in the microwave.

Remote sensing systems can be broadly divided into active and passive sensors. Active remote sensing systems emit a directional energy pulse that interacts with a surface and then returns to the sensor. Information is determined about the surface based on the length of time it takes for the pulse to return, the strength of the returned pulse, and other attributes such as a change in polarization. The two

Forestry, Figure 1 Poplar leaf (left) and canopy reflectance (right). Leaf scale spectra are shown for a *Populus deltoides* x *Pinus nigra* hybrid and compared to two soils and Poplar wood (labeled NPV). Important biochemical absorptions are marked with arrows including chlorophyll (480 and 680 nm), water (980, 1,200, 1,450, and 1,900 nm), and lignocellulose (broad regions at 2,100 and 2,300 nm). Spectra on the right show how reflectance changes with increasing LAI, including an increase in NIR and decrease in red reflectance. Liquid water bands at 980 and 1,200 nm are enhanced as light encounters more leaves with an increase in LAI (Roberts et al., 2004) (Adapted from Davis and Roberts, 1999).

Forestry, Figure 2 Spectra of four broadleaf tree species, three conifers, bracken fern, senesced grass, and rock/soil, including multiple spectra of several of the species (*left*). Spectral differences within a plant species illustrate that spectra are often not unique, but vary with architecture, illumination, or other factors. Map of plant species at Wind River, Washington, generated using 2003 AVIRIS data (*right*).

primary active remote sensing systems used for forestry applications are radio detection and ranging (radar), which uses wavelengths of electromagnetic radiation longer than a millimeter, and light detection and ranging (lidar), which most often uses NIR lasers (0.9–1.064 μm). Active remote sensing is the primary tool used for mapping forest structure (e.g., tree height, crown properties, cover, and aboveground biomass). Passive remote sensing systems measure electromagnetic radiation that is either reflected solar radiation or emitted from the surface. Passive remote sensing systems include aerial photography and airborne or spaceborne scanners that measure a few to many wavelengths of light. Passive remote sensing systems play a greater role in mapping changes in forest cover, forest health, and plant chemistry. Both passive and active remote sensing methods are employed at the ground level, including the use of hemispherical photographs to estimate crown closure and LAI and laser range finders and ground-based lidar to estimate tree height (Davis and Roberts, 1999).

Remote sensing applications

Forest inventories

One of the primary remote sensing forestry applications has been to aid in the development of forest inventories. Forest inventories are designed to quantify important

properties of forest stands, including stand density (the number of trees per unit area), crown closure, average crown diameters, tree heights, and species composition (Avery and Burkhart, 1983). Species composition can be determined using dichotomous photointerpretation keys based on such measures as branching patterns, crown shape, the presence or absence of leaves, and color for color or color-infrared film (Heller and Ulliman, 1983). Tree height can be estimated using stereoscopic techniques, or geometrically from information on sun angles, viewing geometries, and shadows cast by trees. Stand volume and aboveground biomass can be estimated given accurate estimates of height, crown closure, and species composition using relationships derived from field methods. Aerial photographs also aid in improved field sampling by providing forest cover area and through improved stratified random sampling. Several national-scale inventory programs have relied extensively on stratified random sampling from aerial photography, including the forest inventory (Analysis Program: FIA: <http://fia.fs.fed.us/>) in the United States. Species-level differences in leaf optical and structural properties make it possible to discriminate individual tree species, using sensors such as the Advanced Visible/Infrared Imaging Spectrometer (AVIRIS: Roberts et al., 2004; Figure 2).

While coarser spatial resolution, spaceborne sensors can provide many important components of a forest

Forestry, Figure 3 Showing how a digital canopy model (DCM) is calculated from a digital surface model (DSM) and bare earth model (digital terrain model: DTM). This DSM was generated from a first return lidar system flown over La Selva, Costa Rica. The DTM was calculated using the same data by searching for ground returns within a fixed search window (Adapted from Clark et al., 2004).

inventory, the greatest advances have been made in the use of lidar. Lidar systems are typically classified as either discrete return or waveform (Lefsky et al., 2002). Discrete-return lidar systems typically illuminate a small area of ground and divide the returning laser pulse into one or more returns defined by major energy peaks in the returned signal (Lefsky et al., 2002). The returned signal typically includes a distance measure and the strength of return (intensity). Waveform lidar systems divide the returning pulse into a large number of predefined height bins, thus capturing changes in the intensity of reflected energy at a uniform vertical height interval. A majority of forestry applications rely on discrete-return lidar due to greater data availability and established utility.

Discrete-return lidar, by measuring vertical canopy structure, provides many of the structural elements critical for forest inventories. Examples include crown closure, calculated as the percentage of crown returns to total area imaged and canopy height, estimated as the difference between a ground return and the highest return for a specific pixel (digital canopy model, or DCM: Figure 3). Crown diameter can be determined provided individual crowns can be identified and tree height can be estimated from the highest return within an identified crown. Crown base height can be determined from lidar (Riaño et al., 2003) and used to estimate crown volume and bulk density (leaves/branches per unit volume). However, one of the most important uses of lidar has been in improved estimates of forest aboveground biomass (Figure 4). Poor knowledge of tropical forest biomass is one of the most important sources of uncertainty in estimating carbon emissions from deforestation (Houghton et al., 2001). Strong correlations between tree height and biomass make

Forestry, Figure 4 Plot of biomass (y) against mean lidar height (x) from four different forests: Wind River (mixed western hemlock and Douglas fir), La Selva (tropical rain forest), Yellowstone (Lodgepole pine), and SERC (mixed broadleaf deciduous). SERC included courtesy of Keely Roth of UC Santa Barbara.

Forestry, Figure 5 Plot showing spectra of important canopy fuels including green leaves (GV) and litter, branches and stems (NPV). Plant litter, branches and stems are readily distinguished from soils based on their spectral shape. As LFM declines, NIR canopy reflectance decreases, chlorophyll absorption becomes muted, and SWIR reflectance increases. Arrows point to important wavelengths used to estimate changes in canopy moisture.

it possible to estimate biomass from lidar height returns. Lidar intensity can also be used to provide species compositional information, especially when given a combination of leaf-on and leaf-off data (Kim et al., 2009). While

Forestry, Figure 6 Relative greenness for July 20–27, 2009. Areas of below average greenness are shown in various shades of red, and areas with above average greenness are shown in various shades of green (Data from <ftp://ftp2.fs.fed.us/pub/ndvi/>, retrieved from <http://wfas.fire.org/content/view/30/47/>).

a majority of forestry applications have relied on discrete-return lidar, similar high-quality height and biomass estimates have been derived from waveform lidar systems, such as the airborne Laser Vegetation Imaging Sensor (LVIS) (Drake et al., 2002) and the Geoscience Laser Altimeter System (GLAS) onboard ICESAT (Lefsky et al., 2005). Waveform lidar is particularly important because it can be deployed in space and used to estimate biomass from forests that cannot be imaged using airborne systems.

Wildfire fuels and forest fires

Another major remote sensing application in forestry is fire, where remote sensing provides information on fuels, fire danger, fire occurrence, and fire impacts. Improved

knowledge of changing fuel properties and the global incidence of fire is widely considered one of the greatest weaknesses in current global climate models and the ability to quantify fluxes of carbon between the biosphere and atmosphere (Running, 2008). Fires require fuels to burn and are limited by the presence of water; thus, important fuel properties include the mass of fuel, their arrangement in space (depth and packing), their size distribution and geometry, and the amount of water in living and dead tissue (Pyne et al., 1996). Forests can be divided into two important fuel classes, crown and surface fuels. The most extreme fires burn through crown fuels. A common practice is to assign fuel properties using a fuel model, which is typically mapped using image classification. Two of the most common systems used in the United States were proposed by Anderson (1982) and

Forestry, Figure 7 Showing a high-resolution true color pan-sharpened image from Geo-Eye-1 (*left*) and a map of *green*, *red*, and *gray* attack phases of mountain pine beetle generated using a maximum likelihood classifier (*right*) (Adapted from Dennison et al., (2010)).

Scott and Burgan (2005), consisting of 13 and 40 models, respectively. These models can be mapped using a variety of passive optical remote sensing systems but have most often been mapped using Landsat Thematic Mapper (TM) data. Because passive optical systems only image canopy tops, they cannot measure surface fuels obscured by the canopy or other important structural variables. However, these can be estimated statistically (Keane et al., 2001). This is the approach currently used by the Landfire program (<http://www.landfire.gov/>) to estimate understory fuels, canopy bulk density, tree height, and crown base height from Landsat TM and biophysical gradients (i.e., aspect, elevation), trained using field data and fire history.

In shrubland systems, many important fuel properties can be estimated directly from remote sensing because the canopy is the primary fuel (Roberts et al., 2003a; Figure 5), including live fuel moisture (LFM: Dennison et al., 2003) and fuel condition (live to dead fuel ratio, Roberts et al., 2003a). A number of sensors have been used to estimate LFM, including Landsat TM (Chuvieco et al., 2002), AVIRIS (Dennison et al., 2003), and the Moderate Resolution Imaging Spectrometer (MODIS: Peterson et al., 2008). MODIS is particularly important in that these data provide information on how LFM changes seasonally.

Prefire fuels are static, typically assigned to a fuel model where the only dynamic element is dead fuel moisture estimated from meteorology. Fire danger, however, is dynamic, varying with changing vegetation and atmospheric conditions. Most fire danger indices, such as the Keetch-Byrum Index (Keetch and Byrum, 1968), rely exclusively on meteorology. However, dynamic changes in fuels can be determined using remote sensing. One example is the use of MODIS to estimate seasonal changes

in LFM (Peterson et al., 2008). Another is relative greenness (RG: Burgan et al., 1998), in which the greenness of a pixel at a specific time is compared to its historical range derived from a long time series. RG is routinely calculated by the US Forest Service using the Normalized Difference Vegetation Index (NDVI) applied to Advanced Very High Resolution Radiometer (AVHRR) as part of its Wildfire Assessment program (WFAS: <http://wfas.fire.org/content/view/30/47/>; Figure 6). RG is also used as an input into the Fire Potential Index (FPI), a danger index calculated from RG and fuel model derived 10 h fuels and dead fuel moisture of extinction (Burgan et al., 1998).

An important element of fire fighting and forest-carbon accounting is the ability to map the presence of fire. Active fire mapping includes fire detection and estimation of important fire properties, such as fire temperature, area, or fire radiative power (FRP). Satellite-based fire detection relies primarily on the Mid-IR, in which fires emit substantially more electromagnetic radiation than cooler background pixels or reflected solar radiation. Example Mid-IR fire detections include daily 1 km observations using AVHRR (3.55–3.93 μm : Setzer and Malingreau, 1996), sub-hourly 4 km observations using Geostationary Operational Environmental Satellite (GOES, 3.9 μm band; Menzel and Prins, 1996), and two or more daily observations from MODIS, an active fire product similar to AVHRR that takes advantage of additional wavelengths and spatial information to reduce false detections (Giglio et al., 2003). Another important MODIS fire product is FRP, an index correlated to biomass consumption (Wooster et al., 2005), calculated using a modified form of Stefan-Boltzmann's equation applied to the difference between background radiance and fire-elevated radiance in the MODIS 4 μm band (Kaufman et al., 1998). Fire temperature and area can be estimated based on the

Forestry, Figure 8 Maps showing changes in mature forest, pasture, and secondary forest in a portion of Rondonia, Brazil, between 1988 and 2008. Landsat TM data were classified using an approach described by Roberts et al., 2002, modified to reduce errors in secondary forest due to illumination and confusion between mature forest and old secondary forest. The 2008 image is included, courtesy of Michael Toomey of UC Santa Barbara. In these two Landsat scenes, mature forest declined from 76 % (41,940 km²) to 39.6 % (21,851 km²), while pasture increased from 15.5 % (8,720 km²) to 43.7 % (25,665 km²) of the area shown. Secondary forests nearly doubled from 6.5 % (3,600 km²) to 12.2 % (6,740 km²) over this same period.

spectral shape of fire-emitted radiance measured by several sensors, including AVIRIS (Dennison et al., 2006).

Immediately following a wildfire, critical questions include how much area was burned and the severity of damage. Measures of burned area and fire severity are critical in that exposed soil following wildfire is prone to erosion and mass movement, while the potential of recovery may vary depending on the intensity and frequency of fire (Barro and Conard, 1991; Zedler et al., 1983). Common fire severity measures are typically calculated using sensors such as Landsat and include the Difference Normalized Burn Ratio (DNBR) as an example (Key and Benson, 2006; Van Wagendonk and Lutz, 2007). DNBR responds to spectral changes due to an increase in exposed soil, surface ash, and dead plant material. Global estimates of burned area are also critical in that

they capture the global incidence of fire disturbance and provide a means for estimating carbon emissions from burned areas. A number of global burned area products exist including one produced using MODIS (Roy et al., 2005).

Forest health

Spectroscopic changes in leaf reflectance (i.e., pigment damage, water loss), and forest structural changes, such as leaf shedding or defoliation, offer the potential of using remote sensing to map the presence of forest pathogens (Pu et al., 2008). Remote sensing has a long history of use for mapping forest health, initially through the use of aerial photography, but more recently using airborne and spaceborne passive remote sensing systems (Wulder

et al., 2006). Examples include the use of multispectral remote sensing to map defoliation due to various species of budworms (Radeloff et al., 1999), adelgids (Franklin et al., 1995), bark beetles (Wulder et al., 2006; Dennison et al., 2010: Figure 7), and gypsy moth (Townsend et al., 2004). Multispectral and hyperspectral remote sensing have been used to map the distribution of forest pathogens such as *Phytophthora*, which causes diseases such as sudden oak death syndrome (Pu et al., 2008) and Swiss needle cast.

Land-cover mapping, forest degradation, and forest conversion (deforestation)

One of the most important roles of remote sensing for forestry has been in tracking changes in the world's forests, either through forest removal (deforestation), degradation, regrowth, afforestation (tree planting), or natural disturbance (i.e., Hurricane Katrina). Forest areas, consisting of at least 40 % canopy cover by woody plants taller than 5 m, increased an average of three million ha/year between 1990 and 2000 in temperate regions, but declined by an average of 12 million ha/year between 1980 and 2000 in tropical regions (Millennium Ecosystem Assessment, 2005). Much of this information has come from passive remote sensing systems, such as the Landsat TM, MODIS, AVHRR, and SPOT-4. Loss of forest cover underestimates actual human impacts because it does not take into account forest degradation, in which forest integrity is reduced by fire, selective logging, or fragmentation. In the Amazon, annual increases in degraded forests are estimated to exceed deforestation (Nepstad et al., 1999).

One of the most intensively studied areas of the humid tropics is the Amazon Basin, which contains the largest remaining tracts of undisturbed tropical rainforest globally and in which a majority of the deforestation has occurred during the era of routine satellite observations (Roberts et al., 2003b). Tropical rain forests are particularly important because they house some of the world's highest biodiversity and store more carbon than any other terrestrial ecosystem (Dixon et al., 1994). Within the Amazon Basin, some of the highest deforestation rates have occurred in the state of Rondonia, which began to undergo rapid conversion as early as the mid-1970s and continues to experience rapid forest loss today (Figure 8).

Summary

Remote sensing has numerous applications in forestry. Older, historical applications relied primarily on interpretation of aerial photography for forest inventories. More recently, newer airborne and spaceborne active and passive sensors have greatly expanded the utility of remote sensing in forestry. Examples include lidar, which can provide forest structural parameters such as tree height, crown volume, and stand biomass at accuracies that are equal to, or exceed, ground-based measures. Regional to global estimates of changes in forest cover have also been made possible by remote sensing,

providing critical measures of changes in carbon stocks and fluxes needed to better understand human environmental impacts and better manage resources. Several operational remote sensing products contribute to improved assessment of fire danger, fire management, fire severity, and postfire recovery.

Gamma radiation; Gamma rays; High-energy photons;
High-energy radiation; X-radiation; X-rays; γ -rays

Definition

X-radiation. Electromagnetic radiation with wavelength λ shorter than ultraviolet light but longer than γ -rays, $0.01 \text{ nm} \leq \lambda \leq 10 \text{ nm}$.

Gamma radiation. Electromagnetic radiation with energy higher (or, equivalently, shorter wavelength/higher frequency) than X-radiation.

Introduction

X-rays and gamma rays are the shorter wavelength or, equivalently, the higher-energy side of the electromagnetic spectrum. The separation of these two bands is quite conventional: X-rays are considered to have an energy from that of ultraviolet light to the binding energy of inner electronic shells of atoms, whereas above this value there are gamma rays which, broadly speaking, are produced by nuclear activity. For the sake of simplicity, we name as X-radiation those electromagnetic waves with wavelength λ between 10 and 0.01 nm, while gamma rays are assumed to have a value of λ below 0.01 nm. A common way of describing gamma and X-radiation is by the energy expressed in units of electron volt (eV), where 1 eV is the energy acquired by an electron which passes through a difference of potential of 1 V. With this definition, X-rays have energies between about 100 eV and 100 keV (1 keV = 1,000 eV). The relation between the

wavelength in nm and the energy of photons expressed in eV is given by:

$$E = \frac{1239.84}{\lambda_{nm}} \text{ eV}. \quad (1)$$

X-rays were discovered by Wilhelm Roentgen in 1895 as a new kind of emission obtained by the interaction of accelerated cathode rays, that is, electrons, with a target (Shamos, 1987). Their characteristics were a relatively long range and the propagation in straight lines, even in the presence of a magnetic field, which suggested to rule out the hypothesis that X-rays were charged particles. However, it was not earlier than 1912 that the real nature of X-rays as short wavelength electromagnetic radiation came out. Max von Laue showed that X-rays are diffracted by crystal lattices thus proving that X-rays are actually electromagnetic radiation with wavelength comparable to lattice spacing. Gamma rays were discovered by Paul Villard in 1900, who recognized the presence, beyond the α -rays (helium nuclei) and β -rays (electrons), of a component unaffected by magnetic field and scarcely absorbed in the emission of radioactive materials (Gerward, 1999). Also in this case the definite proof that gamma rays are photons with short wavelength came from their diffraction on crystal lattice.

Interaction of X-rays and gamma rays with matter

The short wavelength makes the behavior of gamma and X-radiation much similar to that of discrete particles. Notwithstanding, there is a fundamental difference in the interaction with matter, that is, photons are destroyed when they interact whereas charged particles lose energy continuously.

There are three main processes through which gamma and X photons interact with matter and the probability of occurring of each depends on the energy of the radiation.

In the low-energy part of the X-ray band (soft X-rays), the prevailing interaction is with electrons in inner shells of atoms via the photoelectric effect (or photoabsorption). An electron (named photoelectron) is extracted from the atom with a kinetic energy equal to the difference between the energy of the photon and the binding energy of the electron. Only interactions with electrons bound with an energy lower than that of the photon are possible, and therefore, inner electronic shells are being involved only for increasing photon energy. The contribution of the most internal shell is always predominant with respect to the outer ones. The probability of interaction with a certain shell, that is, the cross section of the process σ , is a steep decreasing function of energy, $\sigma \sim E^{-3.5}$. This dependency is characterized by an abrupt increase of σ as soon as the energy is sufficient to extract photoelectrons from a more inner shell (*absorption edge*). The probability of photoelectric absorption has a strong dependence on the atomic number Z ($\sigma \sim Z^5$) and thus, heavy elements absorb photons with a much more efficiency. The ejection of the photoelectron leaves the ionized atom in an excited status with a vacancy in an inner shell. It can decay via two major processes: the ejection of a fluorescence photon or the ejection of a self-ionization electron (named Auger electron). In both cases, the total energy released is just below the binding energy of the photoelectron. The detection of fluorescence emission is a powerful tool for determining the composition of materials because each element produces radiation with a characteristic pattern, that is, only at those energies which correspond to transitions between its own electronic shells. Therefore, by measuring the energy and the intensity of fluorescence photons, it is possible to identify the atomic elements and their abundance without destroying the sample under test.

At energies higher than the binding energy of most inner electrons (belonging to the K-shell), the probability of photoabsorption decreases quickly. When the energy is tens of times the K-shell energy, namely, between a few tens to a few hundreds of kilo electron volts depending on the atomic number of the material, the prevailing interaction of photons becomes the Compton effect. In this case, the photon is scattered off an electron and the former transfers a part of its energy to the latter. Even if electrons in materials are bound in atoms, for what concern the process of interaction they can be regarded as to be free, because the binding energy is in any case negligible with respect to the energy of the photon. By the conservation of the energy and of the momentum, the energy of the scattered photon E' can be calculated as a function of the scattering angle θ from the energy of the incident photon E :

$$E' = \frac{E}{1 + \frac{E}{mc^2}(1 - \cos \theta)}. \quad (2)$$

The energy acquired by the electron is the difference between E and E' . The probability of scattering and the

angular distribution of photons are described by the Klein-Nishina formula:

$$\frac{d\sigma}{d\Omega} = \frac{1}{4} \left(\frac{e}{mc^2} \right)^2 \frac{E'^2}{E^2} \left(\frac{E}{E'} + \frac{E'}{E} - \sin^2 \theta \right). \quad (3)$$

Another process of interaction between photons and matter is possible, that is, the pair production. If the photon has an energy higher than two times the rest mass of electrons (>1.022 MeV, $1 \text{ MeV} = 1,000 \text{ keV}$), the photon can split into an electron-positron pair. A third body, usually the field of a nucleus but also that of an electron, must be present to allow for the conservation of both energy and momentum, and it can absorb a part of the initial photon energy. Above some tens of MeV, pair production is the most probable interaction and the cross section becomes basically independent from energy.

Interaction of X-rays and gamma rays with Earth's atmosphere

Earth's atmosphere strongly absorbs high-energy radiation, especially in the soft X-ray range. The fraction of photons which pass through it without interacting, that is, the transparency T , as a function of energy is calculated by using the attenuation coefficient μ , whose value can be found in the literature (see, e.g., the "XCOM: Photon Cross Sections Database," Berger et al.). If the depth of the medium is x and ρ is its density, we have:

$$T = \exp(-\mu\rho x). \quad (4)$$

In Figure 1, we report the attenuation coefficient for the Earth atmosphere as a function of energy. The absorption

Gamma and X-Radiation, Figure 1 Attenuation coefficient as a function of energy for Earth's atmosphere. The contributions of photoabsorption (dotted line), of Compton scattering (dashed line), and of pair production (dash-dot line) are distinguished. It is assumed a composition of N₂ (78.1 %), O₂ (20.9 %), and Ar (0.01) (NASA's Earth Fact Sheet). The value of the attenuation coefficient is retrieved from XCOM database (Berger et al.).

is dominated by photoelectric effect, Compton scattering, or pair production at different energies, but its value remains significant all through the spectrum. For example, the attenuation length, defined as the distance at which the transmission is reduced to $1/e$, is 0.23 cm at 1 keV, and the transparency of 1 cm is about 1 % (the density of the atmosphere is assumed to be $1.2 \times 10^{-3} \text{ g/cm}^3$). At higher energies, the absorption is less effective but even at the minimum of the attenuation coefficient around 40 MeV, the attenuation length is only a few hundreds of meters. Moreover, in the range of maximum transparency, the prevailing interaction is the Compton scattering. The radiation interacting with atmosphere is scattered forward with typical angles around 30° and with an energy significantly lower than that of the original photon. Therefore, even if a significant number of photons can survive a thickness of a few kilometers, any spectral or imaging information is lost. As a consequence remote sensing is not an effective tool in these energy ranges for the study of the surface of our planet. This is true for the Earth but not necessarily for other planets: Any celestial body, satellite, or minor body, without an atmosphere, is a potential target for remote sensing in X-/gamma rays – actually a few such studies of remote sensing have been performed and are planned for future space missions.

Detectors for X-/gamma rays

Modern detectors allow to measure X- and gamma radiation with a fine sensitivity (Leo, 1994; Lutz, 2007; Knoll, 2010). Spectroscopy, at the level of 1 eV, and imaging, with a spatial resolution up to 1 μm , are the more developed fields, particularly in the soft X-ray band, but also polarimetry is progressing. X- and gamma rays can be detected only after they have interacted with matter via one of the processes described above, which destroys the initial photon and results in the transfer of its energy to one or more electrons. These electrons propagate in the matter while being scattered by interactions with atomic nuclei and slowed down by interactions with atomic electrons. The energy lost along the path ionizes atoms, producing other electrons, and excites electrons of external shells, which shortly afterward decay and emit UV photons. Electrons extracted by ionization propagate at short distance because they have a very low energy, and hence, the result of the interaction of the photon is a small cloud of ion-electron pairs close to the interaction point and a small flash of UV photons.

We can classify detectors in the following three groups:

Detectors that collect the charges produced by ionizing electrons

One way to detect high-energy photons is to measure the charge deposited in the sensitive volume of the instrument by the electrons produced in consequence of the initial interaction. These charges are produced near the point where the photon interacted and are proportional, in number, to the energy of the photon. Moreover, they

are produced along the path of initial electrons, which contains information on the polarization of the photon. For example, the average energy necessary to the electrons to produce other electron/ion pairs in a gas by ionization is 20–25 eV, and therefore, the energy of a photon of 10 keV is converted in around 400 electrons. An electric field is applied in the sensitive volume of the instrument to drift the electron/ion pairs toward an anode/cathode which collects them. To overcome the noise of read-out electronics, often the pairs are multiplied before collection (of a factor spanning from 10^3 to 10^6 and above) in a region with an intense electric field, which accelerates the electrons so that they can ionize other atoms.

The *proportional counter* was the first device developed for detecting high-energy radiation, capable to measure the energy of individual photons, and it can illustrate very well the functioning of detectors that collect the charges produced by ionizing electrons. The sensitive volume is a chamber filled with a gas, where photons are absorbed and electrons are drifted by an electric field to an anode wire (15–50 μm thick) at high voltage. The field close to the wire is very high and accelerates the electrons that collide with atoms producing more electrons. The original cloud of electron is amplified of a factor 10^3 – 10^5 and is collected by the anode wire, while the ions are collected by other wires or by the box of the detector acting as a cathode. This is the basic function of proportional counters. With the use of many wires, they can act as imaging devices with a resolution down to 0.1 mm. The energy resolution is of the order of 20 % at 6 keV and scales with the square root of the energy.

Semiconductor detectors are another type of instrument which measures the charge produced as the result of the photon interaction. Instead of gas, the sensitive volume is a junction of a crystalline semiconductor (mostly silicon and germanium) inversely polarized. When an ionization cloud is produced inside the depletion layer of the junction, the electrons and holes are immediately collected at the electrodes. Since the energy to produce an electron/hole pair in silicon is 3.4 eV, photons of the same energy produce more charges in a semiconductor than in a gas, and this results in an enhancement of the energy resolution. Another advantage is that solid-state instruments are more compact with respect to gas detectors of comparable efficiency.

Semiconductor detectors are usually used without charge multiplication and hence need very low-noise electronics. This requires a low leakage current, a low capacity of the detector, and an operation at low temperature. Since the depleted layer is the actual sensitive part, it is enhanced by building junctions on two sides of an intrinsic, high-resistivity crystal. The capacity is reduced by reducing the surface of the read-out anode, which means detectors with a smaller surface or instruments which exploit a drift field to collect the charges produced in a large volume on a smaller anode (*silicon drift detector*; see below). Imaging detectors can be built by dividing a detector into regions each one with a dedicated electronics to read out the signal. This can be

done in one dimension with the so-called microstrip detectors or in two dimensions with the so-called pixel detectors. By increasing the number of pixels, the encumbrance, the power consumption, and the difficulty to bond each pixel with its electronic chain with 100 % efficiency has oriented the technology toward an X-ray adaptation of the charge-coupled device (CCD). In this case, the charge produced by each absorbed photon is collected and temporarily stored in the pixel closer to the interaction point, but the read-out of the pixels occurs sequentially with a single low-noise electronics. The potentials of the pixels are modified periodically to repeatedly shift the charge from the pixel to its neighbor and, eventually, to the output where the charge is preamplified and converted from analog to digital. A CCD devoted to X-rays is substantially the same of a CCD for optical application with some minor changes: (1) A window in the entrance prevents the optical photons to reach the sensitive volume, since it would be saturated by the low-energy electrons generated from the absorption of visible/UV photons. (2) The depletion layer is made thicker to increase the efficiency. (3) The dead layers are minimized in order to minimize the absorption of X-rays. While in an optical CCD each photon creates 1 (or 0) electron and the charge collected in the pixel is proportional to the number of impinging photons, a CCD for X-rays is usually discharged very frequently so that the probability to have more than one photon detected in the same pixel is low and the charge measured from the pixel is proportional to the energy of the photon. Therefore, the CCD is an excellent imager (down to resolutions of the order of 10 μm) and an excellent spectroscopic device (down to resolutions of the order of 150 eV). The major limitations are in the surface that cannot exceed a few square centimeters and in the time resolution that cannot be better than a fraction of milliseconds because of the relatively long time required to transfer the charge of the whole matrix of pixels to the output without losses. A recent evolution of CCDs, still in the development stage, is the *advanced pixel sensor* that reads out the charge without transferring it, with a more parallel read-out and a better energy resolution. More in general the CCD suffers the limitations due to the use of silicon as absorbing material, which becomes quite inefficient above some tens of keV, the actual value depending on the thickness. To detect photons of higher energies, detectors have been studied based on materials of higher atomic number such as GaAs and CdTe, but the technologies have not arrived to the level of development of CCDs yet. Other alternative technology is the *silicon drift detectors* where the charge produced is promptly drifted to the output and the coordinate in the drift direction is measured from the drift time, the drift velocity being known. These have a good energy resolution at room temperature but are compatible only with one-dimensional imaging. A further improvement is the development of *avalanche silicon detectors* that, by exploiting the small difference in the mobility of electrons and holes, can perform a proportional multiplication of the charge.

Detectors that measure the light

X-ray photons can also be detected by measuring the light emitted as a consequence of ionization/excitation processes in suitable crystals. These photons are typically in the UV band and are absorbed in few tens of microns, making impossible their direct detection. However, if crystals are doped with elements that create suitable metastable levels, the absorption of the UV photons creates new photons shifted to longer wavelength. The latter are capable to travel across the crystal to an optical window without being absorbed. A photomultiplier with its electronics detects the light, giving an electrical pulse whose height is proportional to the number of photons collected from the cathode and thence to energy released in the interaction.

Scintillators to detect X- and gamma rays are based on inorganic crystals. The most common have been for years NaI (thallium activated), the CsI (thallium or sodium activated), because of good efficiency and high light yield. The $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ (that does not require activation) is most common to detect higher-energy gammas but has a poor light yield. The more recently discovered LaBr_3 (cerium activated) is nowadays the best performing material since it combines a high quantum efficiency with a high light yield that results in a higher-energy resolution. Scintillators are usually employed to detect hard X-rays (>10 keV) and soft gamma rays. They are suitable to achieve large volumes, and smaller crystals can be made position sensitive when coupled with multi-pixel photomultipliers. Larger crystals in the form of bars or disks can be made position sensitive by recording how light is shared by different photomultipliers in different parts of the crystal. Gamma cameras for CAT are a classical application of this method.

Detectors that measure the heat

After the very first interaction, all the energy absorbed from the original photon is eventually converted into heat. If a crystal is small and is kept at very low temperature, where the specific heat is extremely small, also the small amount of energy carried by an X-ray photon is sufficient to produce a measurable increase of the temperature. The microcalorimeters (or X-ray bolometers) are based on this effect. The detector is conceptually composed by an absorber that converts the X-rays, a thermometer in good thermal contact to it and a weak link to a thermal bath to restore the initial condition after the photon absorption. Although the more mature technology is to use semiconductor thermistors to measure the small temperature variation of the absorber, the more promising devices exploit a superconductor kept just below the critical temperature. The heat is sufficient to induce the transition from superconducting to normal state and the change of the current flowing in it is detected by a SQUID (Superconducting Quantum Interference Device). The total energy absorbed is derived from the sequence of the

transition as mapped by the SQUID. This is the Transition Edge Sensor, nowadays, the best performing detector in terms of energy resolution (the current record is 1.8 eV at 6 keV). The development of large matrices of TES and of the read-out of individual pixels is the new frontier and the step needed to give practical application to this technology.

Optics and other imaging techniques

X-ray and soft gamma rays can be focused by means of suitable reflective mirrors like visible light, even if with quite severe limitations. The main difference is that high-energy radiation is reflected only if the grazing angle is below a certain threshold of the order of a few degrees, and this value decreases while increasing energy. This is because the index of refraction at these energies is very close to one. The critical angle above which reflection substantially does not occur is larger for materials of higher atomic number, and indeed it is roughly proportional to the square root of the density of the reflecting material. For this reason a heavy and malleable material as gold is used. As an example, in Figure 2 the reflectivity of a mirror made of gold is reported as a function of the grazing angle and for different energies between 0.5 and 8 keV. Unfortunately, the use of high Z materials causes also a large drop in the reflectivity for energies close to the absorption edges because of the high probability of photoabsorption. This can be filled with a suitable coating on the reflecting material, that is, a material of different atomic number which can reflect X-rays in that particular energy band.

The possibility of reflecting X-rays only for angles below a few degrees implies that the telescope must have a long focal length. This makes the telescopes rather cumbersome. The cost of such a device is also very high, because each reflective surface is to be manufactured with very low roughness, comparable to the wavelength of the radiation to be reflected, precisely aligned and supported by a mechanical structure which provides an adequate stiffness.

X-ray telescopes find their most important use in astronomy since they enable to resolve extended sources and crowded regions, reduce the background, and provide an adequate collecting area. The optics comprises many nested and concentric shells which are formed by two surfaces, the first is a paraboloid and the second is a hyperboloid. The radiation is focused in the focal plane after two reflections on the two surfaces. This configuration, named *Wolter type I*, allows to produce sharp images even off-axis and to reduce the focal length and so the volume (see Figure 3). Inner shells contribute less to the total area because of the smaller radii, but external ones can provide a significant contribution only at low energy since they must reflect photons at larger angles. This actually causes a fast decrease of the effective area with energy, and as a matter of fact, these telescopes can work only below 10–15 keV.

Gamma and X-Radiation, Figure 2 Reflectivity for gold as a function of the grazing angle and for different photon energies. Solid, dotted, dashed, dot-dash, and dash-dot-dot refer to radiation at 0.5, 1.0, 2.0, 4.0, and 8.0 keV, respectively (Data from Henke et al. (1993)).

Gamma and X-Radiation, Figure 3 Sketch of a telescope for X-ray astronomy. Tens of concentric shells are nested and each contributes to the total area, even if external shells can provide a significant contribution only at low energy because of the larger reflection angles required. X-rays are reflected two times on a paraboloid and on a hyperboloid surfaces to provide good imaging capability even off-axis and to reduce the focal length.

The most advanced X-ray telescope is that onboard the Chandra X-ray Observatory, orbiting the Earth since 1999 (see the Chandra X-ray Observatory website). It was designed to achieve the outstanding angular resolution of 0.5 arcsec, and this has required a focal length of 10 m. The telescope comprises of four nested paraboloid/hyperboloid shells which provide a collecting area of 400 cm² at 1 keV. The working energy range is between 0.1 and 10 keV, and only the telescope with the support required to keep aligned the mirrors weighs about 1 t.

A new technology, that is, the multilayer coating, allows to focus X-rays with grazing incidence optics up to hundreds of keV. Instead of a single material with a coating, the shells are made of stacked alternating layers of low and high atomic number materials, deposited via vacuum processes such as evaporation or sputtering. Each layer has a thickness of the order of 1–10 nm which, acting as a crystal with such lattice spacing, diffracts X-rays. Diffraction is a phenomenon which occurs when an electromagnetic wave encounters a spatially repeated structure, such as a grating, with spacing comparable to its wavelength. For X-rays, this occurs with crystal lattices which typically have spacing of the order of a few angstroms (1 Å = 0.1 nm). The planes of the crystal act as reflecting surfaces and the radiation sum, in phase, in those directions which make the difference of optical path between reflections on different planes an integer value of wavelength. Bragg's law relates the energy and the angle at which the diffraction can occur:

$$E = \frac{nhc}{2d \sin \vartheta} \quad (5)$$

where h and c are Planck's constant and the speed of light in vacuum, respectively, d is the crystal lattice spacing, ϑ is diffraction angle, and n an integer which indicates the order of diffraction. Multilayer optics can reflect photons at higher energy, or at larger glancing angles, than "classical" telescopes. By substituting $\vartheta = 1^\circ$ and $d = 1$ nm in Equation 5, it results that the energy diffracted is 35 keV (for $n = 1$). This is a great improvement with respect to single-layer optics, by which photons are reflected at angles larger than 1° only below a few kiloelectron volts. The diffraction from the single layer is nearly monochromatic since, for a fixed value of the spacing of the layer d , the energy is also fixed except for the diffraction order. To diffract continuum spectra, the thickness of the layers is gradually decreased with depth so that the total response is the convolution of nearly monochromatic lines at different energies. Multilayer optics in X-ray astronomy was tested for the first time between 5 and 80 keV by the NASA mission NuSTAR, which was launched in 2012 (Harrison et al., 2013).

Above the hard X energy range, the imaging of radiation cannot be performed with multilayer optics, because it is difficult to make layer with thickness below 1 nm and low roughness. The most promising technique to concentrate soft gamma rays is the use of Laue lenses: photons pass through crystals and are diffracted at grazing angles on the lattice, whose spacing is of the order of a few angstroms (Laue geometry). Laue lenses actually do not focus the image on a focal plane but they just concentrate the radiation. Although the image of a point source on-axis is really a punct, the quality of the image basically depending on the alignment of crystals which compose the lens, it appears like a ring off-axis. Since diffraction on crystal is nearly monochromatic, the efficiency for continuum spectra is increased, at the expense of the

image quality, with the use of mosaic crystals, which are composed of small domains slightly and regularly misaligned acting as independent crystals. Laue lenses are at the moment in development stage, and their use can be expected in the near future.

Imaging of hard X- and gamma rays can be performed also with *coded masks*. These are an evolution of the simple pinhole cameras: The direction of photons is reconstructed by the shadow projected on a sensitive plane. A coded mask instrument is composed of a mask, which is divided in elements, and of a position-sensitive detector. The elements are arranged in a predetermined pattern; some of them are transparent to the radiation to be detected, while the others are opaque. The shift of the mask shadow with respect to center and the distance between the detection plane and the mask enable to reconstruct the direction of impinging photons. The former is measured with a detector with a spatial resolution better than the size of the mask elements. If there is more than one source, the shadows projected by each are summed but the arrangement of the mask elements is chosen so that in any case the position of the sources can be reconstructed without ambiguity by means of a deconvolution process. The intensity of each source is proportional to the "strength" of the corresponding shadow, while the angular resolution is dictated by geometrical parameters, such as the spatial resolution of the detector, the size of the mask elements, and the distance with the detection plane. As a matter of fact, angular resolutions are limited to a few arc minutes because better values would require long focal length and hence quite large volumes.

Coded masks provide a low cost and compact solution to image high-energy radiation up to soft gamma rays, even if the sensitivity of a focusing instrument is always better for an equal collecting area. A coded mask detector measures as a whole the shadow, and hence the noise, of all sources. As a result, the noise which affects the single source is the sum of all contributions, while focusing instruments resolve them spatially. Moreover, the actual geometrical area of the detector in a coded mask device is always larger than its collecting area because about a half of flux must be absorbed by the mask. To reach a large collecting area, an even larger sensitive area is required and this implies a higher background. On the contrary, the flux of sources detected by instruments inserted in focal planes are affected only by the background in the small region where photons are concentrated, that is, the point spread function of the telescope. An application where coded masks are largely used is the imaging of a large fraction of the sky. Grazing incidence telescopes have a field of view smaller than 1 square degree, while a single-coded mask instrument can cover even more than one tenth of the sky, and hence, the entire sky coverage can be performed with a small cluster of detectors.

Another interesting possibility to build large field of view and sensitive instruments is the use of *lobster eye* optics, which is based on the same principle as the

eye of crustaceans (Angel, 1979). The optics is composed of an array of square channels, which are arranged so that their axes are orthogonal to a spherical surface with a radius R . The internal surfaces of channels are made reflective and a true image is formed by those rays which experience an odd number of reflections on both the couples of parallel walls of the channel. Lobster eye lenses are optically equivalent to a concave spherical mirror of radius R and indeed the focal plane is also spherical, with a radius equal to $R/2$. Photons which are reflected an even number of times, also if in just one direction, produce a linear image, parallel to the sides of the channels and passing through the focused image, and, together with photons which are not reflected, are to be regarded as an additional noise. The diagonal of the channel is also the diameter of a point source image on the focal plane, because rays focused by any channel emerge parallel from it with a beam size equal to the diagonal. In principle, lobster eye optics can have a field of view as large as desired up to 4π steradian, that is a complete angular coverage, because there is not any preferred direction, but actually there are technical limitations to build spherical optics and detectors. Also the angular resolution can be very good, and it can be of the order of arc minutes or below. It is basically determined by the ratio between the size of the channel and the focal length, that is, $R/2$.

Lobster eye telescopes are built by exploiting slumped lead glass microchannel plates (MCP, Fraser et al., 1993). Coatings such as iridium or nickel are used to enhance the reflectivity, and the reflection up to hard X-rays has been reported (Price et al., 2002a). An improvement to the basic design is also the packing of a pair of MCPs to form an approximate Wolter type I optics, with each MCP composed of square channels arranged radially (Willingale et al., 1998; Price et al., 2002b). This design improves the performance from many points of view, such as better imaging capabilities and higher effective area, but the field of view is narrower because a preferred direction is introduced by the system.

Recently, lobster eye optics has been also developed with metal ribs coated with gold (Gertsenshteyn et al., 2005). The possibility to polish the walls of the channels allows for the diffraction up to hard X-rays (up to 40 keV) and has opened the way for a number of applications. One of the most interesting is the possibility to inspect objects in a fast and nondestructive way with a portable instrument. This comprises of an X-ray generator, which illuminates the material, and a detector in the focus of lobster eye optics. Photons which are scattered back toward the detector allow for imaging different materials in the object, since the probability of scattering depends on the number of electrons and then on the atomic number. Such an application requires hard X-rays, which are quite penetrating and interact with matter predominantly with Compton scattering. Moreover, the use of a lobster eye telescope allows to collect enough photons in a reasonable time without the use of a cumbersome grazing incident multilayer optics.

At even larger energies, the interactions produce high-energy electrons that are highly penetrating. In experiments active above 50 MeV photons are converted on a thin layer of a high Z material (W or Pb) into an electron-positron pair. These two particles propagate through a tower of tracking silicon detectors. From the analysis of tracks, the original vertex of interaction is reconstructed and the direction of the original photon is derived. Eventually the pair is absorbed on a thick scintillator to measure the energy.

The Earth from outside: X- and gamma rays from atmosphere

The atmosphere of the Earth seen from space is an intense source of X-rays and gamma rays. Also an intense flux of X-rays and γ -rays falls on the atmosphere from the space: Most of them come from the cosmic diffuse background plus many cosmic X-ray sources, and for the half of the Earth exposed to the Sun, they also arrive from solar flares and steady coronal emission. Some of these photons are absorbed by photoelectric effect, while at higher energies the dominant interaction is the Compton effect. A fraction of photons, of the order of 10 % around 80 keV and decreasing at lower and higher energies, is backscattered to space with a significant shift toward longer wavelengths. But the largest component of photons emitted by the atmosphere derives from the interactions with cosmic rays, which are energetic particles coming from a number of classes of astrophysical sources. Therefore, even though atmospheric emission is usually named “albedo” also in X- and gamma rays, the meaning of this term is quite different from the usual optical definition because actually photons emitted are, for the largest part, not reflected.

Cosmic rays have a large flux with a spectrum extending up to very high energies but quickly decreasing at increasing energies. They are composed mainly of protons (i.e., nuclei of hydrogen for ~ 89 %), α -particles (i.e., nuclei of helium for ~ 10 %) plus nuclei of higher atomic number elements (for the lasting ~ 1 %). In paths of the order of few tens of grams per square centimeter, which correspond by dividing by the density of the upper layers of the atmosphere to a height of a few tens of kilometers, these particles collide with the protons or the neutrons in the nuclei of atmosphere constituents, losing a part of their energy and producing short lifetime particles named pions. The neutral pions π^0 decay into two photons, while charged pions π^+ and π^- decay into μ^+ and μ^- mesons, that further decay into electrons and positrons, plus a bunch of elusive neutrinos, that have a very low probability to further interact. Due to conservation of momentum, all these products (photons and electrons) have still directions close to the original direction of the cosmic ray particle. The particles and the photons produced after the first interactions have sufficient energy to interact again and generate further particles, giving rise to a so-called shower. We have, therefore, a bunch of photons

and particles moving downward and continuously interacting, increasing in number and decreasing in energy. After crossing a certain amount of atmosphere, the components of the shower lose energy by photoelectric absorption and by ionization, and the number of particles/photons starts to decrease. Eventually only a few μ mesons arrive to the ground. Also, as long as the shower develops, the angular distribution increases and some photons are backscattered. While most of the energy of the shower is lost in the atmosphere, a certain fraction of photons, nuclei, and electrons move upward and succeed to escape. This is the main constituent of the so-called albedo. For satellites in low Earth orbit, between 400 and 2,000 km, this is a significant source of instrumental background. In the past, many semiempirical formulas have been given to describe the albedo. More recently, given the presence of excellent codes to simulate all these interactions and the good knowledge of the Cosmic ray spectra, detailed computations have been performed of the X-/ γ -ray fluxes at different depths. Sazonov et al. (2007) derive from its simulations that the spectrum of X-/ γ -ray albedo from the atmosphere in the range 25–300 keV is well fitted by the function:

$$\frac{dN_\gamma}{dE} = \frac{C}{\left(\frac{E}{44 \text{ keV}}\right)^{-5} + \left(\frac{E}{44 \text{ keV}}\right)^{1.4}} \text{ photons/keV} \quad (6)$$

The spectrum peaks around 50–60 keV. At lower energies we have a fast drop, due to the fact that at lower energies photons are absorbed, and the emission involves thinner and more external layers of the atmosphere. When compared with the sky, the Earth as seen from the space is very bright in γ -rays, while in soft X-rays is dark. The constant C in Equation 6 depends on the magnetic latitude, on the phase of the solar cycle and on the zenith angle. Formulas to compute this normalization can be found in Sazonov et al. (2007). At the peak around ~ 60 keV, the flux integrated on all directions is of the order of 4×10^{-3} photons/(cm² s keV) at the magnetic equator and around six times higher at a magnetic latitude of 65°. Also some nuclear gamma ray lines in the MeV range are present, but they are a minor fraction of the total flux.

The remote sensing of the Earth from space in the hard X/soft gamma band is mainly probing the interaction of Cosmic Rays with the upper layers of the atmosphere. This can identify a method to study the atmosphere of other planets and has been actually used with some interplanetary probe.

A particular case is that of terrestrial gamma-ray flashes (TGFs). They were discovered by the Burst and Transient Source Experiment aboard the Compton Gamma Ray Observatory (Fishman et al., 1994) and are very short bursts of γ -rays, lasting from 0.5 to 4 ms, arriving from the direction of Earth and characterized by a much harder spectrum than typical celestial gamma-ray burst. The very short duration of these events puts a requirement on time resolution and on triggering capability of the instrument, which is usually satisfied by modern satellites. More

events were reported by the Reuven Ramaty High Energy Solar Spectroscopic Imager (Smith et al., 2005) and AGILE arrived to detect a TGF event with a maximum energy of 43 MeV (Marisaldi et al., 2010). The geographic distribution of TGF is peculiar: There is a concentration at very low latitudes, with a higher frequency above the dry land than above the oceans.

While the fact that TGFs are originated within the atmosphere seems out of question, a large debate is in progress about their nature. There is a certain similarity with X-/ γ -radiation observed on ground from lightning. Dwyer (2008) proposes that the energetic seed particle production most likely involves either relativistic feedback or runaway electron production in the strong electric fields associated with lightning leaders or streamers. The phenomenon would originate at relatively low levels in the atmosphere (10–20 km). The Atmosphere Space Interaction Monitor, aboard the International Space Station, will study TGFs, trying to connect them with storms and with the elusive Transient Luminous Events. ASIM includes a coded mask and an array of Hard X-ray detectors to better determine the location of the phenomenon (Neubert et al., 2006).

Remote sensing of solar system bodies: planets, satellites, and minor bodies

If the remote sensing (RS) of the Earth is limited to few topics that do not include the solid or liquid surfaces, the situation is different for planets or other bodies of the Solar System without an atmosphere or with one thin enough to be transparent to X- and gamma rays. Actually experiments of RS have been embarked aboard missions flying by and orbiting around some of these bodies.

In the domain of X-rays, the spectrum of photons from the surface can determine, through the fluorescence lines and the absorption edges, the chemical composition and the abundances of the surface. Depending on the energy, this analysis can probe layers spanning from a few tens of microns for Si to, for instance, 1 mm for nickel. One major problem is that planetary surfaces do not emit X-rays but they can only reprocess those coming from an external source. Usually solar flares are providing such a source but, for an interpretation of fluorescence spectra in terms of quantitative chemical composition, a good knowledge of the impinging spectrum is mandatory. However, this is not very easy to achieve because every solar flare has its own spectrum. In the gamma-ray band, a celestial body can be itself a source of radiation deriving from the intrinsic radioactivity of the rocks or from that produced by the impact of cosmic rays, both primary and solar. Since the cosmic rays are ubiquitous, their characteristic affects less the results than the impinging spectrum in X-rays spectroscopy. The gamma-ray lines provide unique signatures for the presence of elements in a layer of the order of 10 cm.

A gamma-ray spectrometer (GRS) was mounted aboard Apollo 15 and Apollo 16. It was based on a NaI(Tl)

scintillator read with a photomultiplier sensitive in the 0.065–27.5 MeV range. Orbiting around the Moon, these instruments covered about 20 % of the surface. They had no directionality and a row mapping was achieved simply on the basis of proximity to various regions at various orbital phases. By comparison of data accumulated in orbit with samples of the Moon collected from various missions in different sites and returned to the Earth, these data allowed to assess that anorthositic fragments are the main constituents of the Moon's surface.

The Near Earth Asteroid Rendezvous Shoemaker spacecraft orbited around asteroid 433 EROS from February 14, 2000, and after about a year it landed on the surface. It included an X-ray/gamma-ray spectrometer. The X-ray detector was a set of three proportional counters capable to measure spectra in the 1–10 keV range. The gamma-ray detector was made of an internal scintillator of NaI(Tl) with a shield made of BGO, each read by its own photomultiplier. The X-ray spectrometer detected the X-rays by solar flares backscattered with superimposed absorption edges and fluorescence lines. From a modeling of solar flares spectrum, the composition of surface layers was derived. The gamma-ray spectrometer detected nuclear lines from a few elements. This can be considered the first case of remote sensing of a reasonable completeness.

After this first experience, X-ray and gamma-ray spectrometers were included in planetary probes. SMART-1, an ESA mission that orbited around the Moon from 2003 to 2006, included the Demonstration of a Compact Imaging X-ray Spectrometer (D-CIXS), an X-ray spectrometer based on silicon detectors with a narrow field collimator (Grande et al., 2007). An important improvement is the presence of a detector of solar flares (Huovelin et al., 2010), providing the input spectrum needed to convert the measured spectra into abundance of elements. A similar instrument, Chandrayaan-1 X-ray Spectrometer (CIXS) was launched on October 22, 2008, on India's Chandrayaan-1 mission to the Moon (Swinyard et al., 2009).

Another X-ray spectrometer (XRS) and gamma-ray spectrometer (GRS) were aboard the Japanese satellite Kaguya/SELENE operative in 2007–2008 (Hasebe et al., 2008; Okada et al., 2009). The spectral quality was much better than previous instruments because it used CCDs for XRS (combined with a solar flare monitor) and a high-resolution germanium detector for the GRS.

MESSENGER is a mission inserted in orbit around Mercury in 2011 (Schlemm et al., 2007) and, since then, mapping elemental abundances in the surface of the planet (Nittler et al., 2011). The X-ray spectrometer onboard is based on silicon detectors set with a collimator to detect the X-rays from the Sun and another set to detect those reflected by Mercury. A germanium detector is dedicated to gamma rays and neutrons (Goldsten et al., 2007).

DAWN mission to Vesta and Ceres includes a gamma-ray and neutron detector to detect gamma-ray lines (Prettyman et al., 2004). A first map of elemental abundances of Vesta minerals, acquired with low altitude orbits

was published (Prettyman et al., 2012). So far we only described experiments that measure X-ray and gamma-ray spectra, in some case with a field limiter, but never imaging. The first imager devoted to remote sensing will be hosted aboard the Mercury Planetary Orbiter of the BepiColombo mission (Fraser et al., 2009). The mercury imaging X-ray spectrometer uses two focusing instruments composed of two identical silicon active pixel sensors and two X-ray optics based on microchannel plates. One telescope is a lobster eye lens, while the other is in a Wolter type I configuration. With this instrument X-ray remote sensing would significantly decrease the gap with respect to remote sensing in other wavelengths.

Summary

X-rays and gamma rays cover the short wavelength side of the electromagnetic spectrum. Their more frequent interactions with matter are the photoelectric absorption, the Compton scattering, and the pair production, whose relative probability depends on the energy of the photon and on the atomic number of the material. X-rays and gamma rays are detected with proportional counters, semiconductor detectors, scintillators or bolometers. X-rays can be reflected at grazing angles by very smooth surfaces. This allows for the manufacture of telescopes that can arrive to good angular resolutions on very small fields of view. To perform imaging on large field of view particular telescopes, named lobster eye, can be used. At higher energies and for wide field imaging systems combining a mask designed with a particular code and position-sensitive detectors are used.

Our Earth observed from the space is a bright source of X-rays and gamma rays, mainly originated by the interaction of cosmic rays with the top layers of the atmosphere. Therefore, remote sensing in these bands is mainly probing this region. On the contrary remote sensing in X-ray and gamma-ray band is performed on bodies of the Solar System without atmosphere (the Moon, Mercury, asteroids) or with a thin one (Mars), with instruments aboard flying-by, orbiting, or landing probes. This technique is expected to contribute significantly to the study of chemical composition of planetary surfaces.

Definition

Geodesy. The branch of Earth Sciences concerned with the size, shape, orientation, and gravity field of the Earth.
Global Navigation Satellite Systems (GNSS). Satellite navigation systems that provide geo-spatial positioning with global coverage.
Very Long Baseline Interferometry (VLBI). A radio-astronomical technique utilizing globally distributed antennas having independent atomic clocks. The antennas collectively form an interferometer or synthetic aperture.
Gravimetry. That branch of the geosciences concerned with the measurement of the force or acceleration of gravity.
International Terrestrial Reference Frame (ITRF). The internationally agreed terrestrial reference frame, defining longitude and latitude at a number of reference points, thus forming the basis for much global positioning.

Introduction

Geodesy is comprised of three “pillars”: the shape of the Earth, its orientation, and its gravity field.

Geodesists first consider the global scale and then proceed to the local. Regional mapping, much geophysics, and positioning with the Global Positioning System (GPS) require first that global aspects be well understood. This has driven geodesy to become perhaps the most international of the sciences.

International services and projects, organized under the auspices of the International Association of Geodesy (IAG) (<http://www.iag-aig.org/>), are needed to coordinate work which cannot be conducted on national or

*Her Majesty the Queen in Right of Canada

continental scales. Technique-specific services today include the International GNSS Service (IGS) (<http://www.igs.org/>), the International VLBI Service for Geodesy and Astrometry (IVS) (<http://www.ivscc.gsfc.nasa.gov/>), the International DORIS Service (IDS) (<http://ids.cls.fr/>), and the International Laser Ranging Service (ILRS) (<http://www.ilrs.gsfc.nasa.gov/>). The International Earth Rotation and Reference Systems Service (IERS) (<http://www.iers.org/>) is responsible for producing products based on information from these services. Products include reference frames and Earth's orientation information. The IAG International Gravity Field Service (IGFS) (<http://www.igfs.net/>) coordinates activities related to the Earth's changing gravity field.

The Global Geodetic Observing System (GGOS) (<http://www.ggos.org/>) is an IAG effort to further integrate international geodetic activities. GGOS contributes to the Global Earth Observing System of Systems (GEOSS) (<http://www.earthobservations.org/>) and is consistent with the Integrated Global Observing Strategy (IGOS) (<http://www.igospartners.org/>) (see *Global Earth Observation System of Systems (GEOSS)*).

The shape of the earth and reference frames

The Earth's shape is approximately that of an oblate spheroid with an equatorial radius of about 6,378 km. This radius is approximately 0.3 % greater than that at the poles, or 21 km. The topography varies from about +9 km (Mount Everest) to −11 km (Mariana Trench). The relative size of these variations accounts for the appearance of the Earth from space as a nearly perfect sphere.

For geodesists, the shape of the Earth is described by the location and velocity of reference points in a geocentric terrestrial Earth-fixed reference frame, called the International Terrestrial Reference Frame (ITRF). Locations may be given in geocentric X, Y, and Z coordinates, or in terms of latitude, longitude, and height above an ellipsoid that approximates the Earth's shape.

The ITRF and the International Terrestrial Reference System (ITRS) are products of the IERS. The ITRS defines the frame origin, scale, orientation, and time evolution. The ITRF is a practical realization of the ITRS: three-dimensional coordinates and velocities of reference points on the surface of the Earth. The ITRF is updated periodically as more observational data is obtained or with improvements in theory or analysis.

The IERS publishes conventions to be followed by contributors, providing agreed numerical standards, reference frame information, geophysical models, and models for propagation of observables (McCarthy and Petit, 2003).

The ITRF approximates a no-net-rotation surface, resulting from an averaging of tectonic and other motions on the Earth's crust. As a result, the velocity of a point in the ITRF will be the sum of that due to the motion of the local tectonic plate, intraplate motion/deformation, and other local effects relative to a global mean of motions.

The ITRF is produced from the combination of data from a number of different techniques. Of interest to users are the low cost and easily deployed Global Navigation Satellite System (GNSS) receivers, dominated today (2008) by the Global Positioning System (GPS). There is more than one GNSS constellation. Apart from the operational US GPS system, Russia's GLONASS is near full operational capability, the upcoming European GALILEO system holds much promise, and China may extend the regional Beidou/Compass system to provide global coverage. Regional Navigation Satellite Systems have been proposed by Japan and India.

GNSS augmentation is the use of additional information to improve that broadcast by the satellites. Augmentation can occur in real time or in postprocessing. A trade-off has always existed between latency and accuracy, but improvements in both are occurring at a very rapid pace. User-obtained accuracy is dependent on many factors, including mode of operation (static or dynamic), single or dual frequency observations, length of observation, and equipment used. Postprocessing of data sets (from anywhere on Earth) can now be done on the internet to cm-level accuracy with a delay of only 90 min after data collection (Mireault et al., 2008). The Wide Area Augmentation System (WAAS) is a real-time augmentation system operated by the US Federal Aviation Administration that provides accuracy at nearly the 1 m level. WAAS is available in the Continental United States as well as most of Canada and Alaska. Similar systems exist in much of the world.

The primary benefit of global reference frames is in navigation, positioning, and Earth science studies. For example, the driving force behind the development of the GPS constellation was the military need for precise positioning anywhere on Earth. Use of global reference frame information benefits users who integrate georeferenced data collected by different people for many different purposes at different times. Related fields include mapping, surveying, and hydrography (see *Geological Mapping Using Earth's Magnetic Field*).

In remote sensing, georeferencing may be performed through occupation with GNSS receivers of identifiable points on imagery. With continued improvement of Earth Observation resolution, accurate orthorectification is increasingly important. Additionally, remote sensing satellites or aircraft may be dynamically positioned via GNSS. Augmentation to decimeter-level precision of kinematic GPS data collected during airborne remote sensing can be easily performed (Mireault et al., 2008). Precise global reference frames are required for many scientific efforts, including global sea-level rise studies and satellite laser altimetry missions.

As precision in geodesy has advanced, the ability to observe contemporary change has arisen (Chao, 2003). Networks to monitor motion are established near tectonic plate boundaries, in regions experiencing glacial isostatic adjustment (postglacial rebound) or other regions of interest. Regional, national, continental, and global networks

with varying data latency, precision, and spatial density exist to respond to geoscientific needs (see [Subsidence](#)).

Geodetic reference frame analyses require accurate modeling of many geophysical effects which affect the observables or instruments, including tidal effects, atmospheric loading, and antenna offset/deformation (McCarthy and Petit, 2003).

Effects on geodetic signals (electromagnetic radiation), experienced while traversing the Earth's ionosphere and troposphere, are very significant. Ionospheric effects can be precisely quantified by observation of multiple frequencies since the refractive index is a strong function of frequency. Taking advantage of this, GNSS systems are being deployed as ionospheric sensors (see [Ionospheric Effects on the Propagation of Electromagnetic Waves](#)).

Hydrostatic delays and those due to water vapor in the troposphere corrupt observables in a manner that is difficult to correct for due to the chaotic nature of the weather. Extended data collection and sensitive analysis are necessary to separate these effects from the desired geodetic information (see [Water Vapor](#)).

GNSS systems are deployed in meteorology in two ways. First, the analysis of fixed continuously operating GNSS systems yields information on atmospheric pressure (hydrostatic delays), including water vapor content above the antennae. Second, limb sounding of GNSS satellite signals from other satellites in lower orbit provides information on atmospheric density profiles (see [Limb Sounding, Atmospheric](#)).

Earth's orientation

The orientation of the Earth is given by the relationship between the terrestrial reference frame and another representing inertial space. This relationship involves the rotation of the Earth, polar motion (geographic position of the rotation axis of the Earth), and the coordinates of the rotation axis in the celestial sphere ("celestial pole"). Each of these Earth orientation components exhibits some degree of motion that is currently unpredictable.

Polar motion includes a drift of about 12 m per century superimposed on the Chandler Wobble (having a diameter of about 15 m and a period of approximately 433 days) and a smaller seasonal signal of 8 m diameter. The slow drift of the pole is due to large-scale mass redistribution such as postglacial rebound.

Motion of the celestial pole is the sum of precession (one cycle each 25,800 years) and nutation (a series of many shorter period terms).

Following the invention of accurate clocks based on crystal oscillators during the Second World War, it soon became clear that the Earth's rotation was irregular. Instrumentation was in place to measure the changing Earth rotation prior to the introduction of conventional Universal Time in 1960. The rotation rate may be expressed as its inverse, the length of day.

The Earth system ("solid Earth," oceans, atmosphere) approximates a closed system which conserves angular

momentum. Thus, the counterpoint to variations in Earth's rotation/orientation ("solid Earth") can be seen in atmospheric and oceanic changes. The Earth's orientation thus provides a global sensor of mass movements both within (the "solid" Earth is not solid) and outside the Earth.

The IERS publishes Earth Orientation Parameters which relate the ITRF with the International Celestial Reference Frame (ICRF). The ICRF approximates an inertial reference frame and is primarily expressed by a set of coordinates of quasars, extragalactic objects at great distance from the Earth. This great distance ensures that quasars show no apparent movement (unlike visible stars) and are thus nearly ideal points of reference. The astronomical Very Long Baseline Interferometry (VLBI) technique is critical to establish the ICRF and its link to the ITRF (i.e., the Earth's orientation). Satellite systems are crucial in establishing the origin of the ITRF.

The historical link between time and longitude continues today in the use of GNSS systems as time references (telecommunications) and for precise time transfer, most notably among timing laboratories used in Universal Time definition.

Physical geodesy

The study of the gravity field of the Earth is known as physical geodesy. The force of gravity varies at the surface of the Earth due to distance from the geocenter, density variations in the crust, and other effects.

The Earth is neither homogeneous nor smooth, so the gravitational potential at its surface varies spatially. To describe these variations, we define an equipotential surface (the "geoid") which corresponds to the mean ocean surface of the Earth ("mean sea level"). The geoid is typically described by a smooth ellipsoid plus local "geoid undulations" which can be as large as 107 m (NIMA World Geodetic System Technical Report 2000) ([Figure 1](#)).

Heights on mapping products are given as heights above sea level; thus, they are representative of the inhomogeneous Earth and are useful for management of water. Heights have traditionally been obtained by sequential spirit level measurements from a reference point (e.g., tide gauge), but today it is possible in many regions to use GNSS and a geoid model. Geoid models are used with measurements of sea-surface height to identify sea-surface topography associated with currents (see [Sea Surface Wind/Stress Vector](#)).

Gravity field information contributes to petroleum and mineral exploration, as mineral deposits will have characteristic gravitational signatures. Similarly a characteristic gravitational signature occurs where continental crust meets oceanic crust; thus, gravimetry is used to support efforts to define limits to continental shelves, crucial for delimiting national borders under the United Nations Law of the Sea (see [Solid Earth Mass Transport](#)).

Geodesy, Figure 1 The Earth's gravity field derived from GRACE satellite data (Image courtesy of NASA's Gravity Recovery and Climate Experiment, The University of Texas at Austin's Center for Space Research).

Gravimetry (at the surface, airborne, or from space) can be considered a remote sensing tool that sees through solid objects. Gravity combined with other information (magnetic, seismic, surface geology, etc.) is used to produce three-dimensional maps of potential oil- or mineral-bearing regions. New technologies fusing gravity data with other remotely sensed information, such as hyperspectral surface geochemistry or **RADAR** interferometry, have the potential to further contribute.

Models of the Earth's gravity field are also used in satellite orbit determination and to predict missile trajectories.

The Earth's gravity field has a temporal structure as well. An instrument on the Earth's surface will record large diurnal changes resulting from solid Earth tides (on the order of 30 cm), since the instrument will be sensitive to geocentric distance. Gravity measurements on the Earth's surface in regions experiencing glacial isostatic adjustment (postglacial rebound) detect both the rising surface of the Earth above the geocenter and mass redistribution in the mantle.

Other temporal changes in Earth's gravity are associated with hydrology, as these are the largest mass redistributions on a time scale of months to years. Satellite missions such as GRACE (<http://www.csr.utexas.edu/grace/>) are capable of remotely sensing the changing water mass on and in the Earth (Velicogna and Wahr, 2006). Based on observations of the motion of and relative motion between the two GRACE satellites, a gravity field model is determined at regular (monthly) intervals and expressed in spherical harmonic functions. Such satellites are entirely unlike other remote sensing satellites which

use electromagnetic radiation, frequently incorporate CCD sensors, and produce images composed of pixels.

Conclusion

Geodesy is one of the oldest and most international of the sciences. Rapid technological improvements have transformed our capabilities in recent years, enabling exciting new discoveries about the Earth system. It has been argued that there is a space-geodetic "Moore's law" in which we see a tenfold improvement every decade in measurement precision as well as, in some cases, spatial and temporal resolution (Chao, 2003). These advances are opening up new opportunities such as real-time GNSS-based tsunami warning systems and hydrology from satellite gravimetry.

User access to the ITRF is expected to rapidly improve in the near future as the capacity to perform satellite orbit/clock modeling in near-real time becomes a reality and as multiple satellite constellations are integrated. With this will come many challenges as well as opportunities to learn more about the Earth system.

The VLBI community is focused on a new operational model entitled VLBI2010 which promises significant advances in precision with lower cost operations. Similarly the satellite laser ranging (ILRS) community has a modernization effort underway entitled SLR2000. Refer to the respective IGS service websites for additional information.

The GRACE satellites represent a revolutionary new technique for which applications are still being discovered. Next-generation satellites of this type (in the planning stage) will provide significant improvements and will likely lead to many new benefits.

GEOLOGICAL MAPPING USING EARTH'S MAGNETIC FIELD

Vernon H. Singhroy¹ and Mark Pilkington²

¹Applications Development Section, Natural Resources Canada, Canada Centre for Remote Sensing, Ottawa, ON, Canada

²Geological Survey of Canada, Ottawa, ON, Canada

Definition and introduction

The Earth's magnetic field comprises two main components: the core field, caused by motions of the electrically conductive, liquid iron mixture in the outer core, and the crustal field, caused by magnetic minerals within rocks in the Earth's crust. Geological applications focus on the crustal field, which has spatial variations with wavelengths <1,000 km and amplitudes generally <1,000 nT (nanotesla). The separation of core and crustal field is effected through removal of a mathematical model of the core field known as the IGRF (International Geomagnetic Reference Field). The IGRF is based on mainly magnetic observatory, ship- and satellite-based magnetometer measurements and is updated every 5 years. Once isolated, the (crustal) magnetic field can be used to infer the magnetic properties of the rocks within the Earth's crust and hence provide indications of geological structure and composition. Measurements of the Earth's magnetic field for

mapping purposes are carried out on a variety of moving platforms: satellites, ships, airplanes, helicopters, and vehicles. Ground-based, handheld magnetometers may also be used for small-scale surveys. The type of measurement platform will be determined by the size of survey area, its topography, location, and the mapping goals. For geological mapping purposes, airborne (fixed-wing aircraft) surveys are the most cost-effective and informative approach for data gathering.

Geological mapping applications of magnetic field data

The fundamental tenet of geological mapping with magnetic fields is *trends of features in the magnetic field mimic those of the outcropping geology*. This is especially the case where the geology consists of magnetic metamorphic and igneous lithologies (Figure 1). Since surficial cover such as vegetation, soil, desert sands, glacial till, water, and many sedimentary rocks is effectively nonmagnetic, the observed magnetic field can be directly related to the underlying rock types. Although structural features and changes in lithology are reflected in the magnetic field maps, a one-to-one connection between some geological feature, e.g., a pluton, and the resulting magnetic field is not always guaranteed. There must be a contrast in the physical property (i.e., magnetization) between the pluton and its surroundings that is large enough to produce a magnetic anomaly which can be detected by a magnetic survey.

The identification of lithology from magnetic field maps can also be ambiguous as the magnetic properties of a given rock type are controlled by the amount and composition of the accessory minerals present, which only constitute about 1.5 % of crustal minerals (Clark and Emerson, 1991). Accessory minerals are generally ignored in petrological classifications (based on silicate mineralogy), and so specific lithologies may exhibit a wide range of magnetic properties. Nevertheless, individual anomalies may signify the presence of a specific lithology or formation. Patterns of anomalies and the shapes of groups of anomalies may reflect certain lithologies, formations, or geological domains. Since there is ambiguity present in what lithology produces a given anomaly, it is desirable to have some knowledge of the magnetizations of the rock types likely encountered in a given area. This knowledge can come from known (published) compilations of physical rock properties, or preferably, from measurements on samples taken from the area of interest or from adjacent areas.

The magnetization of a rock consists of two components: induced and remanent. Induced magnetization is quantified by the rock's susceptibility and is only produced in the presence of the Earth's magnetic field. Remanent magnetization is a permanent magnetization acquired at some point in the rock's history. Both types of magnetization may be present in a rock, but magnetic anomalies are predominantly caused by induced magnetization. The main contributor to the induced magnetization is magnetite (Fe₃O₄), a member of the magnetite-ulvöspinel solid-solution series known as

Solid black lines faults.

titanomagnetites (Reynolds et al., 1990). The susceptibility of titanomagnetites is effectively zero for ulvospinel contents greater than about 70 % but is significant and fairly uniform for the rest of the series. Other magnetic minerals of lesser importance are hematite ($\alpha\text{Fe}_2\text{O}_3$), common in oxidized igneous rocks and sediments formed in oxidizing conditions, and pyrrhotite (Fe_7S_8), found in basic igneous rocks, low- to medium-grade metamorphic rocks, and sedimentary rocks.

Interpretation methods

How magnetic maps are interpreted depends on the goal of the study, but the aim is always to characterize and classify the magnetic sources that produce the observed magnetic field. Interpretation methods can be divided broadly into two categories: quantitative and qualitative. The difference between the two is that the former aims to estimate the values of some or all of the physical quantities (e.g., depth, shape, magnetization) of the magnetic sources present, while the latter attempts to classify the

magnetic field (or processed versions of it) into regions that can be interpreted in terms of lithology and structure. For geological mapping applications, qualitative interpretation methods are the most appropriate since the aim is to take the magnetic field data and convert them into a pseudo-geological map. Although automated methods for classifying images are available, most magnetic map interpretations of this type are done manually. Quantitative approaches are usually brought into play afterward, to investigate certain anomalies of interest by, e.g., estimating the dip or depth of a given unit.

For geological mapping applications, the magnetic field map (or image) is not the only piece of information available for interpretation. Numerous processing methods can be applied to the magnetic field data to produce transformed data (or images) where certain features that will aid in the mapping process are preferentially enhanced. Several commonly used transformations are described in the following section.

Magnetic maps

Magnetic field maps

An example of a magnetic field map, covering a portion of the Abitibi Greenstone Belt, Quebec, is presented in [Figure 1a](#). The patterns of colors depicted on the map show the strength of the measured magnetic field and hence reflect how strongly magnetized the rocks are; reds denote magnetic highs and blues represent magnetic lows. Trends in the anomalies reflect the distribution of magnetic minerals (predominantly magnetite) in the surface geology in the area.

The character of individual anomalies is dependent on the shape of the magnetized region or source, its depth, and its magnetization. As the distance from the measurement point to the magnetized source increases, the resulting anomaly decreases in amplitude and increases in width or wavelength. Therefore, the field observed in [Figure 1a](#) is mostly caused by the rocks close to or at the Earth's surface, i.e., the outcropping geology. There will be (generally weaker) contributions from deeper magnetized sources, i.e., buried geological units, but these effects can be considered unimportant when using the data for geological mapping purposes. [Figure 1a](#) shows clearly the predominant east–west striking geological trends in this region (see [Figure 1d](#) for the geology), with the more magnetic units (stronger magnetic field) occurring in the south. Some broad correlations can be made: The highest-amplitude magnetic highs on the map are caused by peridotitic rocks of the Roberge formation. Smaller-amplitude highs are associated with ferrogabbros occurring within anorthosite of the Lac Doré formation in the southeast. Magnetic lows or subdued zones are generally associated with the felsic Blondeau and Waconichi formations. On the other hand, some mafic lithologies do not show a significant magnetic effect, e.g., the Bourbeau and Ventures rocks. Often, more mafic lithologies have more Ti-rich magnetites which results in lower susceptibilities. Within the Gilman formation (volcanics), many magnetic trends can be seen suggesting possible subdivision into mafic and felsic flows. The correlation between geology and magnetic anomalies is made clearer through transformations of the magnetic field as outlined below and shown in [Figure 1b](#) and [c](#).

Magnetic vertical gradient maps

The vertical gradient (or first vertical derivative) of magnetic fields has been used since the 1960s to improve the resolution of features on a magnetic map. The vertical gradient can be measured directly when surveying but is more commonly calculated from the magnetic field. Calculating the vertical gradient is similar to high-pass filtering the data, so long-wavelength anomalies (usually associated with deeper features) are suppressed and gradient anomalies produced by near-surface geological features are emphasized. Closely spaced geological units are better resolved because the vertical gradient of a given anomaly is narrower than its magnetic field

counterpart. Consequently, the vertical gradient map is a standard product used in mapping. As with many enhancement procedures, the problem of noise amplification is present when gradients are calculated; thus, some filtering (usually low-pass) may be required.

[Figure 1b](#) shows the magnetic vertical gradient over the study area. Note that the high-amplitude E–W trending anomalies in the southern part of the map are now better resolved; the anomaly widths have decreased and in some cases a single magnetic field anomaly in [Figure 1a](#) is now resolved into two separate gradient anomalies (e.g., at 74° 09'W 49° 58'N).

Tilt maps

The tilt is defined as the arctangent of the ratio of the vertical gradient to the magnitude of horizontal gradient of the magnetic field (Miller and Singh, 1994). The horizontal gradient achieves a maximum near or over source edges and tends to zero elsewhere. The vertical gradient is positive over the source, zero over or near source edges, and negative elsewhere. As a result, the tilt of the magnetic field tends to be positive over sources bodies, zero over source edges, and negative elsewhere. One advantage of the use of the tilt is that, being a ratio, anomalies due to both weak and strongly magnetized sources are given equal weight. Hence, subtle (and often short-wavelength) anomalies are enhanced. Linear and quasi-linear geological features such as faults appear as minima, whereas dykes often appear as maxima in the tilt map.

[Figure 1c](#) shows the tilt of the magnetic field over the study area as a grey shade map (the superimposed dots are discussed below). Note that the broad change from high to low magnetic field values going northward ([Figure 1a](#)) is not apparent on the tilt map. Also, the prominence of high-amplitude (in the south) versus low-amplitude (in the north) anomalies is removed, and all anomalies have similar expressions (amplitudes) in the tilt map. Both of these effects are due to the balancing effect of calculating a ratio of quantities based on the magnetic field.

Contact maps

Mapping the locations of lateral magnetization contrasts, i.e., the edges of magnetic sources, is one of the most basic and useful applications of magnetic survey data in geological mapping. Delineating the extent of units with similar magnetic properties follows the geological mapping approach of dividing the surface into rocks having similar properties. Whether or not the magnetization changes exactly mimic lithological changes, mapping lateral contrasts provides invaluable information on structural regimes, and deformation styles and trends. There is more than one method of contact mapping, each with its own pros and cons. All methods aim to define contact locations based on maximizing a given function over the source body edge. The locations of these maxima can then be plotted over the magnetic field, vertical derivative, etc., to enhance the interpretation. Details on how the different methods are implemented are given in Pilkington and

Keating (2004). No one method has all of the desirable properties for a reliable contact mapper; hence, using more than one approach is always recommended since colocated solutions from different methods provide increased confidence in the reliability of a given contact location and lessen the adverse effects of source magnetization direction, geological dip, and depth extent.

Figure 1c shows contact locations as black dots superimposed over the tilt of the magnetic field. These contacts were computed from the absolute value of the horizontal gradients of the magnetic field in the N–S and E–W directions (Pilkington and Keating, 2004).

Analytic signal maps

The analytic signal is defined as the absolute value of the square root of the sum of the two horizontal and the vertical derivatives of the total magnetic field (Roest et al., 1992). The main property of the analytic signal is it reaches a maximum value directly over lateral magnetization contrasts (contacts) and that this maximum's location is independent of the orientation of the Earth's magnetic field and of the magnetization direction of the bodies. The benefit of these properties is that no assumptions about the nature of the magnetization of the sources are required. However, this is only true for 2D structures. For 3D structures (e.g., intrusives) the shape of the analytic signal is almost but not completely independent of the Earth's field and magnetization directions. The analytic signal gives maxima directly over contacts and sheets (thin dykes). For a thick dyke, two series of maxima slightly offset outward from their true location are observed. As a result, dykes can appear a bit thicker than they really are. The use of derivatives to define the analytic signal accentuates near-surface effects and noise in the data. As a result, the analytic signal maxima often form discontinuous trends, even along seemingly continuous total field anomalies. Nevertheless, the location of analytic signal maxima can be taken to indicate the position of contrasts between differently magnetized bodies and, as such, can be used to locate geological contacts (cf., Pilkington and Keating, 2004).

Shaded relief magnetic maps

Sometimes the intensity and spatial distribution of magnetic variations within a region are such that a magnetic field image may appear somewhat muted, containing little information. Such images can be enhanced using a technique known as shading or shaded relief. The process simulates the effects of light directed on the three-dimensional surface defined by the grid of magnetic anomaly values. The intensity of light reflected back from a slope on the surface will vary according to the steepness of the slope. The proportion of illuminating light reflected back is known as the reflectance and attains a maximum for slopes that are perpendicular to the direction of the light. The overall effect is one of areas of varying brightness and areas of shadow, an effect very

similar to that created by the sun shining over a range of hills. The light direction and its inclination from the horizontal can be varied, thereby providing different images of the same data set. Depending on the direction and inclination, certain features may be enhanced or suppressed. Generally, magnetic features are enhanced when the light direction is oriented at right angles to them.

Magnetic and radar fused image

The fusion of magnetic and radar images has been used to assist in geological mapping and mineral exploration (Singhroy and Molch, 2004). An example of the uses of image fusion techniques is presented.

The Sudbury Basin is one of Canada's richest mining areas, with world-class mineral deposits and the world's oldest (2 billion years), largest, and best-exposed meteorite impact structure. Figure 2 shows the 300 km diameter elliptical impact structure known as the Sudbury. Over the past 100 years, about \$135 billion of nickel and copper ores have been mined from more than 90 mines distributed around the rim of the Sudbury Basin. Current production is about \$2 billion a year.

Much remains to be learned about the structural evolution of the Sudbury Basin and the mineral occurrences around it. The RADARSAT-1 image provides an excellent synoptic view of the topography and structural features of the Sudbury area. Structure is expressed by differential erosion controlled by faults, dykes, and different rock types. The fused RADARSAT and magnetic images shown in Figure 2 are produced from special image processing techniques using the Intensity-Hue-Saturation (IHS) integration procedure (Singhroy and Molch, 2004). The RADARSAT-1 image provides terrain information and the surface expressions of structures seen on the image, which appear as a network of linear features. The low-resolution vertical magnetic gradient image (100 m), obtained from the Geological Survey of Canada, shows geological units as expressed from their magnetic signatures. The variation in the concentration of magnetic minerals can be used to map different rock types. Therefore, the combined RADARSAT-1 and the magnetic image is useful in the geological mapping of structures and rock types. The circular area in red (Figure 2) represents the high magnetic signature of the Sudbury Igneous complex. Magma-filled dykes representing NE–SW trending lineaments also have a high magnetic signature. The other colors shown on the fused image correspond to different rock types with different magnetic signatures. These type of fused image maps are used by geologists and mining companies to facilitate geological mapping and mineral exploration projects.

Interpreting magnetic field maps

Geological mapping from magnetic data is essentially an exercise in pattern recognition. The basic approach is to divide the region into areas that have similar character, based on the amplitude, shapes, and textures seen on the magnetic maps. Areas can be initially divided up based on the

Geological Mapping Using Earth’s Magnetic Field, Figure 2 Fusion of RADARSAT and vertical gradient magnetic image of the Sudbury Basin impact structure, Ontario, Canada. This type of image map is used to map geological structures and rock types for mineral exploration (Singhroy and Molch, 2004).

Geological Mapping Using Earth’s Magnetic Field, Table 1 Magnetic field products and their utility for geological mapping applications

Quantity	Use	Mapping application
Magnetic field	General	Lithology + structure
Shaded relief	Emphasize specific directional trends + fine detail	Mainly structure
Vertical magnetic gradient	Emphasize fine detail	Lithology + structure
Tilt	Emphasize low-amplitude areas	Mainly structure
Analytic signal	Highlight contacts, remove magnetic field inclination effects	Mainly contacts
Contact	Map contacts	Structure + contacts

amplitude of the anomalies, i.e., separating the area into regions where amplitudes are high and nonmagnetic regions where amplitudes are low. Negative anomalies on maps do not necessarily imply negative or reversely magnetized rocks; they generally just show areas of weakly magnetized lithologies. Once amplitude information is taken into account, then the patterns/textures of trends/features within these areas can be evaluated. Different “units” can be distinguished based on the strike of anomaly trends by grouping together regions having similar strike (assuming a constant direction is apparent). Similarly, regions can be defined on the basis of similar texture or pattern of anomalies. The resulting areas do not yet have a geological interpretation; they are merely areas defined by similarities in amplitude, trends, and patterns of anomalies. Broad geological inferences can, however, be made. Outlines of the subdivisions may indicate lithology or structure, e.g., ovoid, magnetic regions suggest intrusions, particularly if they interrupt the

surrounding dominant strike direction(s). Sinuous trends suggest ductile deformation, while truncation of trends or region outlines would suggest brittle deformation and faulting. Inferring rock type in a region defined by the magnetic data requires additional independent geological knowledge, usually from geological mapping within or adjacent to the area of interest. In this process, magnetic anomaly characteristics can be compared and calibrated with the known geology and correlations between the two can be established. Importantly, this comparison may dictate which lithologies can be distinguished and which cannot. It is more likely that more than one lithology will produce similar strength anomalies, since magnetic properties may not vary significantly between different rock types, so this ambiguity will remain in the interpreted map.

No one type of magnetic map will provide all the information to make a complete interpretation. Table 1 lists the most useful map products and what their main

applications are. Clearly, there is overlap between the different products, but since they all provide somewhat independent representations of the original data, it is recommended that all that are available be used in an interpretation.

Landscape geology; Physical geography

Definitions

Uniformitarianism. The assumption that processes operating at present are the same processes that have operated in the past – essentially that “the present is the key to the past.” The utility of the uniformitarianist paradigm for geomorphology depends on the assumption of a roughly constant range of surface environments, which is not true over on timescales comparable to the age of the planet.

Baselevel. The lowest level to which a stream, river, or groundwater can flow. For large rivers it is usually at the river mouth, typically sea level. For enclosed drainage basins, baselevel can be elevated or “perched.” For most landscapes baselevel limits the depth of erosion.

Pediment. Gently sloping surface of bedrock, often disjoint from steeply sloping mountain foothills, which forms a steady-state equilibrium surface of transport for laminar sheetwash flows. They are often veneered by alluvial gravels or soils.

Scarp. Sometimes also called an escarpment, it is a steep difference in slope, forming a cliff that is often the boundary between different physiographic units within a landscape due to differential susceptibility to erosion. A scarp may also form because of differential uplift along a fault.

Dendrochronology. Also called “tree-ring dating,” is a method of scientific dating of timber to specific years by counting the annual growth patterns of tree rings. As a technique, it has proved effective in the calibration of ages determined by radiocarbon dating over approximately the last 8,000–10,000 years.

Bioturbation. The mixing of sediment grains by the action of plants and animals in the soil.

Introduction

Geomorphology is the study of the configuration and history of the surface of the earth and the processes that shape it. As a scientific discipline, its goals are to understand how and why the landscape has come to look the way it does, through an understanding of dynamic physical and chemical processes through time, and to predict how they will shape its form in the future. Its practitioners, *geomorphologists*, traditionally have approached this challenge with empirical field observations, laboratory and field experiments, and by using numerical and analytical modeling. Modern geomorphic techniques include computer graphics visualization and airborne and orbital remote sensing. While in much of the world, especially the United States, geomorphology is taught and practiced as part of the science of geology, elsewhere, especially in the United Kingdom and former commonwealth countries, its practice and teaching has resided within the field of physical geography. Environmental and civil engineering fields also draw heavily from and contribute to the field. Geomorphology is also often central to the analysis of geological hazards. Most recently, *planetary geomorphologists* have turned their attention to studies of the surfaces of other planets and their satellites as the related field of *comparative planetology* has developed, enabled by spacecraft remote-sensing observations over the last 40 years or more.

While *geomorphological* analyses can be traced back as far as the ancient Chinese literature, the first modern Western geomorphic model was developed by the English pioneer in the field, William Morris Davis (1850–1934), who modeled the cycle of landscape erosion, following the earlier *uniformitarianist* thesis of James Hutton (1726–1797). The classic Davisian model involves riverine downcutting (baselevel lowering), followed by general erosion of the surrounding adjacent landscape to a lower elevation (the peneplain), and followed by uplift to restart the cycle. While conceptually valuable, its gross oversimplification limits its utility as a practical tool. Alternative models by Albrecht Penck (Austria, 1858–1945) and son Walther (Austria, 1888–1923; simultaneous uplift and erosion) and Lester King (South Africa, 1907–1989;

pedimentation via scarp retreat – e.g., King, 1967), competed with the classic Davisian cycle approach, but none were universally applicable. Current geomorphic models embrace the geological paradigm of plate tectonics as one of the underlying forces driving the geomorphic engine as it sculpts the earth. For the other planets, geomorphic processes have played out under a variety of exotic (compared to the earth) boundary conditions, including differing gravitational fields, surface temperature regimes (e.g., cryogenic or hyper-thermal), atmospheric conditions, impact rates, and unique tectonic regimes. G. K. Gilbert (1943–1918), the important early American geomorphologist (dynamic equilibrium model), also was one of the first to apply geomorphology to another planetary surface in his analyses of lunar craters from telescopic observations.

During the so-called quantitative revolution in geomorphology in the middle twentieth century, analyses of drainage networks as a fundamental landscape element were prominent. The fundamental modern contribution to the analyses of drainage networks was made by US Geological Survey hydrologist Robert Horton (1875–1945) in his analyses of the hierarchy of branching stream networks, whereby the smallest unbranched tributaries were assigned order unity, and order added arithmetically downstream throughout the network. Subsequently, Horton's model was modified by the American geologist Arthur Strahler (1918–2002) to include the concept of stream power (the higher the order, the higher the power). Subsequent work by Adrian Scheidegger and Ronald Shreve addressed mathematical inconsistencies in the Horton and Strahler schemes, and Shreve demonstrated the topological randomness of drainage basins, from which much of the systematic character of the stream ordering systems devolved. Time-independent steady-state equilibrium for humid temperate drainage basins, proposed by John Hack (1913–1991), stood somewhat in contrast to the erosion cycle models.

Modern geomorphic work has included an emphasis on quantitative techniques in the field and laboratory and on the physical connection between process and form, and particularly the testing of ideas about the *time-dependent* evolution of landscapes (Ritter et al., 2002). The advent of modern radiometric, dendrochronologic, thermal luminescent, and other absolute dating techniques has made this possible. Tectonic geomorphology has also taken on more importance, particularly over the last 40 years or so as plate tectonics has become the dominant paradigm for earth crustal evolution and dynamics.

Geomorphology of the earth

When seen from space, 75 % of the Earth's surface is dominated by its oceans of liquid water, while the remaining 25 % of nonmarine subaerial land, lying mainly in the Northern Hemisphere, where most of the world's population lives, has been the subject of nearly all historical geological and *geomorphological* study. The Southern

Hemisphere is dominated by oceans, some subaerial continental and archipelago land masses (mainly parts of Africa, South America, Southeast Asia, and Australia), and the large, mainly subglacial, island continent of Antarctica.

Despite 200 years of geological and geographical scientific practice, it has only been during the last 40 years or so that detailed mapping and geophysical explorations of the submarine land surface revealed evidence of “plate tectonics,” namely, the presence of intensely volcanic mid-oceanic ridges and their associated parallel-paired geomagnetic domains, along with submarine trenches along continental or island-arc margins (Heezen and Tharp, 1977). Mid-oceanic ridges are where new volcanically generated material accretes to oceanic plates, where trenches harbor deep subduction, and where oceanic crust is consumed beneath other overriding crustal plates. Less dense continental plates form over time as more silica-rich island-arc material generated volcanically at oceanic plate margins accretes, eventually becoming persistent continental cratons, resistant to subduction because of their lower density, thus having the propensity to “float” over more magnesium and iron-rich oceanic plates. Oceanic plates tend to be mobile and are subducted, thus having typical lifetimes of 100–200 Myr, while continental landmasses may persist up to 2–3 Byr, preserving evidence of much of the history of the earth, including some ancient landscapes. Tectonic plates are the Earth's most fundamental geomorphic units.

Geomorphically, submarine oceanic basins areally dominate terrestrial landforms. The main features of oceanic basins are the oceanic ridge and rise systems. Sometimes locally very rugged, they can rise to several km above the average oceanic depth. In the Atlantic Ocean, rise systems exhibit a central rift valley that is at the center of the rise, which is not always true in the Pacific. Older crust within oceanic basins can have gently rolling abyssal hills. Predominantly flat abyssal plains that stretch for thousands of kilometers are usually also covered with accumulated marine sediment. In places they are punctuated by seamounts – conical topographic rises often topped by coral lagoons or residing just beneath the oceans' surface. These are undersea volcanoes formed as island arcs or midplate hot spots, such as the mid-Pacific Emperor Seamount chain, which terminates in the Hawaiian Islands at its southeastern end. Though areally smaller, oceanic margins are another important submarine landform province. “Atlantic style” continental margins tend to exhibit substantial ancient sediment accumulations and a shelf-slope-rise overall morphology, which probably represents submerged subaerial landscapes remnant from the last Ice Age. Continental shelves are usually less than about 100 km in width and have very shallow ($\sim 0.1^\circ$) topographic slopes. Submarine canyons (also probably remnant from the last Ice Age) can deeply cut the continental shelf and slope and terminate in broad submarine sediment fan deposits at the seaward canyon outlet. “Pacific style” oceanic margins, present along the margins

of the Pacific Rim, are even narrower, consisting of a short shelf and slope that can terminate into deep submarine trenches, including subduction zones (e.g., South America, Kamchatka, Aleutian, and Kurile Islands), up to 10 km deep. Shallower “back-arc” basins occur on the overriding plate behind island arcs (e.g., Sea of Okhotsk).

The subjects of classic geomorphological investigations are the Earth’s “subaerial” landscapes. While mainly continental, some important subaerial landscapes (particularly volcanic ones, e.g., Hawaii, Galapagos Islands) exist on oceanic islands. Terrestrial subaerial landform suites are the classic landscapes studied in geomorphology (Snead, 1980). Drainage basins exist at nearly all spatial scales and range from very active drainage basins in humid and semiarid climatic zones to only occasionally active or relict drainages in arid zones. Drainage basin morphology is strongly influenced by a combination of mountain building related to plate tectonics and prevailing climatic regimes (Schumm, 2005).

Land surface volcanic processes produce characteristic landscapes in all climates. They occur mainly at plate boundaries, with isolated oceanic (e.g., Hawaii) and continental (e.g., the San Francisco volcanic field in Northern Arizona, the Columbia and Snake River volcanic plains in the US Pacific Northwest, the Deccan Traps in India) examples occurring away from plate boundaries. Central vent volcanic landforms range from strato-cone volcanic structures to large collapse and resurgent calderas (e.g., Krakatau, Indonesia). More areally extensive and lower subaerial shield volcanoes, formed by more fluid lavas, exist in places like the Hawaiian Islands or the Galapagos Islands, for example (Francis and Oppenheimer, 2004).

The expenditure of energy in the landscape erodes the earth’s surface and transports sediment. Destructional processes, such as rainfall-driven runoff and streamflow, are essentially exogenic processes (i.e., the energy that drives the evaporation and precipitation, and winds that transport water vapor, comes from an exterior source – the Sun). Constructive landscape processes are mostly endogenic – derived from the internal dynamo processes that drive plate tectonics and subsequent mountain building (Bloom, 1998).

In familiar ways, such destructional geomorphic processes work to reduce the “topographic disequilibria” that constructive landscapes represent. For instance, the relatively low and ancient Appalachian Mountains were pushed up during one of the collisions between the North American and European continental landmasses and probably exhibited relief comparable to the Himalayan mountain range today. The former topographic relief represented strong disequilibria and thus potential energy to be converted to kinetic energy by erosive runoff. Once continental collision processes slowed to a stop and tectonic uplift ceased, erosion and surface transport processes (such as rainfall, associated runoff, snowfall, and glaciation) over only a few tens of millions of years reduced the proto-Appalachian Mountains to the gently sloping and relatively low-relief state we see today. Volcanogenic

landscapes are good examples of how competition between destructive and constructive processes sculpts the earth. For example, Mt. Fuji in Japan is an active volcano that erupts approximately every 100–150 years. Fuji’s classic symmetrical conical shape is the result of volcanic eruptions that deposit material, on the average, faster than it can be eroded. When Fuji enters a dormant phase, it will become deeply incised by stream erosion, and it will rapidly lose its symmetric conical profile over a geologically short interval.

Weathering is another key geomorphic process through which consolidated material is broken down into constituent grains by chemical and physical means. Chemical weathering occurs when natural acids act on carbonates, such as limestone or sandstones, releasing the residual silicate grains. Mechanical weathering occurs when the hydrostatic pressure of ice in freeze-thaw cycles overcomes the brittle strength thresholds in rock at microscopic and macroscopic scales. Likewise, salt crystals can exert mechanical energy to break up rocks and can chemically weather rocks, mostly in arid areas. Mineral oxidation, particularly iron-containing minerals, is yet another form of chemical weathering. Biological weathering can take the form of chemical weathering by biogenic acids, particularly in tropical areas. It can also occur mechanically by bioturbation of soils and sediments, as well as by the physical pressure of root and stem turgor in cracks and fissures within solid rock. It is significant that all three main forms of weathering are enhanced or enabled by the presence of water.

Finally, mass wasting is perhaps the most dramatic form of nonvolcanic landscape alteration. The term “mass wasting” is applied to processes such as landslides; creep, snow, and debris avalanches; submarine slides and slumps; volcano-tectonic sector collapses; and scour related to the action of glaciers. While such processes tend to affect only a small part of the Earth’s surface, when they occur near populated areas, their effects can be devastating.

New technology and global geomorphology

Stimulated by the desire to understand the Earth’s history in the nineteenth century, geomorphology evolved from a highly descriptive natural history to a modern physical science by the progressive adoption of analytical techniques and technologies as they became applicable and available for landscape-related science. New airborne survey techniques developed as a result of World War II provided comprehensive information on the topography and near-subsurface structure and composition of landscapes. Improved aerial photography and photogrammetry greatly impacted quantitative approaches to geomorphology. The Newtonian approaches of Strahler (1950, 1952), Bagnold (1941), Horton (1945), and Leopold and Maddock (1953), emphasizing direct observables, and the advent of absolute dating methods, especially radiocarbon methods (Libby, 1955) for time periods more recent than 30Ka BP, had a profound effect on the field, finally allowing accurate estimations of surface process rates. The

expansion of modern technology within geomorphology also facilitated quantitative statistical approaches to landscape analyses (e.g., Schumm, 1956; Melton, 1958; Lubowe, 1964; Shreve, 1975; and Pieri, 1984) and allowed more complex analyses, such as attempts to illuminate the self-organization of landscapes (e.g., Phillips, 1995, 2003, 2009).

Most recently given the proliferation of large (10–100 Tb) databases produced by a new generation of late twentieth and early twenty-first century orbital observational instruments (e.g., Pieri and Abrams, 2004), high spatial and spectral resolution orbital imaging at wavelengths from visible through thermal infrared to microwave detailed stereophotogrammetric, radar, and LIDAR modeling of land surface topography, and relatively frequent temporal sampling are now available. Modern earth orbital missions routinely allow detailed physical and chemical characterization of the Earth's surface at 10–100 m scales, or better (e.g., ASTER, SRTM, EO-1, Radarsat, ICESAT, and others). The emergence and ready availability of remote-sensing technology and its influence on the science of geomorphology have fostered the modern view geomorphology as a “system science” (Church, 2010) with an integrated global perspective, especially among younger *geomorphologists* who are technologically adept.

These new technologies are now being used to monitor and study the dynamics and history of earth surface processes, land use, and societal vulnerabilities at a variety of scales and to synergistically complement in situ field observations, across the planet. Spatial continuity of data is now available down to the centimeter scale over many large areas (Church, 2010). Global topographic databases (e.g., ASTER Global Digital Elevation Model) with resolutions of tens of meters, and for local areas LIDAR imagery, can provide data at almost granular spatial scales. The availability of such thoroughly quantitative measures of the global landscape has opened up possibilities of analytical analysis that were undreamed of just a few decades ago (Lane et al., 1993). One of the most recent remote-sensing-related technologies that have been of critical importance has been the Global Positioning System (GPS). It has provided unprecedented ability to determine location on the Earth's surface, typically to within meters. Especially when combined with radar interferometry, these techniques allow the dynamic nature of rapidly changing topography (e.g., pre-eruption inflation of volcanoes) to come within view. In the aggregate, this postmillennial remote-sensing and measurement technology bonanza has found important application in volcanology, glacial and periglacial processes, hydrology and fluvial geomorphology, mass wasting analyses, coastal studies, eolian studies, and geomorphology as related to climate change. Perhaps most profoundly, the precision and accuracy of such techniques now allow us to document the impact of man as the principal agent of geomorphic change on Earth (Church, 2010; Hooke, 1994, 2000).

Summary

The Earth had liquid water oceans for most of its history, has a highly mobile crust, and a dynamically convecting interior. Its surface has been constantly driven by the movement of the interior causing the periodic conglomeration and separation of continental landmasses, the opening and closing of oceans, and the construction and destruction of mountain ranges. Such globally dynamic geomorphology profoundly impacted the global climate and thus biological evolution in general, and specifically human habitation patterns and the development of civilization. Given that as a species we have been shaped and affected by (and now, ourselves, shape) the patterns and intensity of surface geological processes – geomorphic processes – it is hard to overemphasize the importance of geomorphology as a discipline that offers environmental insights significant to our continued well-being as Earth inhabitants. New emerging techniques and approaches to landscape analyses using remote sensing on a planetary scale offer additional significant advantages for unification of regional geomorphological insights into an emerging global science (Baker, 1986; Short and Blair, 1986; Church, 2010). Such knowledge will most likely be even more important as we try to cope with and mitigate the effects of global climate change on society.

GEOPHYSICAL RETRIEVAL, FORWARD MODELS IN REMOTE SENSING

Eugene Ustinov
Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA, USA

Definition

Forward model. Quantitative tool for simulation of *observables* for a given set of *model parameters*.

Forward problem. System of differential equations with initial and/or boundary conditions, solution of which, the *forward solution*, is used for simulation of *observables*.

Forward solution. Solution of the *forward problem*.

Instrument model. Quantitative procedure for evaluation of *observables* from the *forward solution*, which models

the characteristics of the instrument and the procedure for measurements.

Model parameters. Parameters of the forward problem contained in its differential equations and initial and/or boundary conditions.

Observables. Output parameters of the *forward model*, which simulate the quantities measured in the geophysical retrieval.

Sensitivities. Partial or variational derivatives of *observables* with respect to *model parameters*.

Introduction

A general qualitative description of forward models used in remote sensing, their components, and functions is provided in the entry [Geophysical Retrieval, Overview](#). Two major components of the forward model are as follows:

1. *Forward problem* – provides a quantitative description of physical processes in the object of remote sensing, which result into observable quantities used in the geophysical retrieval. In a general case, the forward problem has a form of a system of equations – differential equations with initial and/or boundary conditions. Its solution, the *forward solution*, serves as an input for the procedure of computation of observables.
2. *Instrument model* – an expression converting the forward solution into observables. In a general case, it has a form of a functional, which maps the forward solution, a function, into the observable, a discrete quantity. As such, the instrument model is not a mathematical problem, which has to be solved. It is an expression, which has to be calculated.

Two major functions of the forward model are:

1. *Computation of observables* – involves application of the instrument model to the forward solution to obtain the observables.
2. *Computation of sensitivities* – involves application of the linearized forward problem and linearized instrument model to obtain sensitivities of observables to retrieval parameters.

Implementation of the second function of the forward model can be accomplished in three different ways:

1. Finite-difference approach
2. Linearization approach
3. Adjoint approach

An upper-level quantitative description of major components and functions of the forward model is provided in this entry along with illustrations based on simple analytic demo forward problem and instrument model.

Forward problem, instrument model, and computation of observables

In the general case, the forward problem represents a set of nonlinear differential equations with initial and/or boundary conditions. In high-level notation, the forward

problem can be written in the form of a generally nonlinear operator equation

$$N[X] = S \quad (1)$$

where the operator N combines all operations on the forward solution X , whereas the right-hand term S combines all inhomogeneous terms. All model parameters are contained either in the operator N or in the right-hand term S , which are some functions of these parameters.

As an example, consider a demo forward problem:

$$\begin{cases} \frac{dX}{dt} + a(t)X^2(t) = 0 \\ X(t_0) = X_0 \end{cases} \quad (2)$$

It has two model parameters: $a(t)$ and X_0 . This problem can be written in the form of Eq. 1, where

$$N[X] = \frac{dX}{dt} + a(t)X^2(t) + \delta(t - t_0)X(t)$$

and

$$S(t) = \delta(t - t_0)X_0$$

and the Dirac δ -function enforces action of the initial condition only at $t = t_0$. This forward problem has an analytic solution

$$\begin{aligned} X(t) &= \left(\int_{t_0}^t a(t')dt' + (X_0)^{-1} \right)^{-1} \\ &= \left(A(t) + (X_0)^{-1} \right)^{-1}, \end{aligned} \quad (3)$$

where

$$A(t) = \int_{t_0}^t a(t')dt' \quad (4)$$

is a primitive function of $a(t)$.

Using similar high-level notations, computation of observables R from the forward solution X can be represented in the form

$$R = M[X] \quad (5)$$

where M is, in general, a nonlinear functional describing the procedure of modeling the observables. In many practical applications, this functional is linear, and the above procedure can be represented in the form of the inner product

$$R = (W, X) \quad (6)$$

where the function W describing this procedure has the same domain of arguments as the forward solution X . It has a meaning of a weighting function, “carving” the

observables from the forward solution and is referred to here as *observable weighting function*.

As an example, consider an observable obtained from the solution of the demo forward problem Eq. 2 in the form

$$R = X(t_1) = \int_{t_0}^{t_1} \delta(t - t_1)X(t)dt, \text{ and } W(t) = \delta(t - t_1) \quad (7)$$

Since the forward solution is available in analytic form Eq. 3, dependence of this observable on model parameters $a(t)$ and X_0 is also available analytically:

$$R = \left(A(t_1) + (X_0)^{-1} \right)^{-1} \quad (8)$$

This analytic dependence will be used to illustrate various applications below.

As a more realistic example, consider a forward model of radiances in the thermal spectral region at the top of a plane-parallel non-scattering planetary atmosphere. The forward problem has the form of a radiative transfer (RT) problem:

$$\begin{aligned} u \frac{dI_v}{dz} + \kappa_v(z)I_v(z, u) &= \kappa_v(z)B_v(z), \\ I_v(0, u) &= 0 \text{ for } u > 0, \\ I_v(z_0, u) &= \varepsilon_v B_{s,v} \text{ for } u < 0 \end{aligned} \quad (9)$$

Here, the forward solution $I_v(z, u)$ is monochromatic intensity of radiation at frequency ν depending on vertical and angular coordinates: depth into the atmosphere z and cosine of the nadir angle of propagation of radiation u . The forward problem Eq. 9 has two continuous and two discrete model parameters: atmospheric absorption coefficient $\kappa_v(z)$, Planck function $B_v(z)$, surface emissivity ε_v , and Planck function $B_{s,v}$. The geophysical parameters of interest, the atmospheric and surface temperature, as well as the composition of the atmosphere and surface, are encapsulated in the radiative parameters of the RT problem, and dependence of the radiative parameters on retrieval geophysical parameters is assumed to be known.

The instrument model here is specified by instrument spectral and angular responses. Assuming for simplicity that these responses are linear and decoupled into $\psi(\nu - \nu_0)$ and $\Psi(u - u_0)$, respectively, the radiances measured at the top of the atmosphere ($z = 0$) are represented as

$$R = \int_{\Delta\nu} d\nu \psi(\nu - \nu_0) \int_{-1}^1 du \Psi(u - u_0) \int_0^{z_0} dz \delta(z) I_v(z, u)$$

Thus, observables in this forward model can be represented in the form of a linear functional

$$R = \int_{\Delta\nu} d\nu \int_{-1}^1 du \int_0^{z_0} dz W_\nu(z, u) I_v(z, u) = (W, I)$$

with the observable weighting function

$$W_v(z, u) = \psi(v - v_0)\Psi(u - u_0)\delta(z)$$

Sensitivities to discrete and continuous model parameters: an overview

The dependence of observables on discrete parameters is essentially that of a function of multiple variables. Thus, the sensitivity of the observable R with respect to a discrete parameter p_k is simply a partial derivative $\partial R/\partial p_k$. If a discrete parameter p_k experiences a variation δp_k , then corresponding variation of the observable has the form

$$\delta_{p_k} R = \frac{\partial R}{\partial p_k} \delta p_k \quad (10)$$

The dependence of observables on continuous parameters is essentially that of a functional dependence on a function. Correspondingly, the sensitivities of observables with respect to continuous parameters are variational (aka functional) derivatives, which can be introduced as follows. Let $F[f]$ be a functional defined in the domain of functions $f(x)$, which, in their turn, are defined in the domain Dx of arguments x . By definition, the variational derivative $\delta F/\delta f(x)$ of the functional $F[f]$ with respect to $f(x)$ is a kernel $K(x)$ in the linear integral relation

$$\delta_f F = \int_{Dx} K(x) \delta f(x) dx \quad (11)$$

and correspondingly

$$\frac{\delta F}{\delta f(x)} \equiv K(x) \quad (12)$$

If the function $f(x)$ is approximated by its values $\{f_j\}$ on a finite-dimensional grid of arguments $\{x_j\}$, then the functional $F[f]$ is approximated by a function of multiple variables $F(f_j)$. Correspondingly, variation $\delta_f \tilde{F}$ can be approximated as

$$\delta_f \tilde{F} \approx \sum_j \frac{\partial \tilde{F}}{\partial f_j} \delta f_j \quad (13)$$

On the other hand, the above integral expression for the variation $\delta_f F$ Eq. 11 can be approximated as

$$\delta_f F \approx \sum_j K_j \delta f_j \Delta_j x \quad (14)$$

where

$$K_j = \left. \frac{\delta F}{\delta f(x)} \right|_{x=x_j}$$

This yields an interrelation between the variational derivative $\delta F/\delta f(x)$ and its finite-dimensional approximation $\partial \tilde{F}/\partial f_j$:

$$\left. \frac{\delta F}{\delta f(x)} \right|_{x=x_j} \approx \frac{1}{\Delta_j x} \cdot \frac{\partial \tilde{F}}{\partial f_j}, \text{ and } \frac{\partial \tilde{F}}{\partial f_j} \approx \left. \frac{\delta F}{\delta f(x)} \right|_{x=x_j} \cdot \Delta_j x \quad (15)$$

Note that the value of the function $f(x)$ at some fixed value of the argument $x = x'$ can also be considered as a functional defined on this function. To find the variational derivative $\delta f(x')/\delta f(x)$, we observe that

$$f(x') = \int_{Dx} \delta(x' - x) f(x) dx$$

Comparison with Eqs. 11 and 12 yields

$$\frac{\delta f(x')}{\delta f(x)} = \delta(x' - x) \quad (16)$$

This definition Eqs. 11 and 12 represents a practical recipe used to derive expressions for computation of variational derivatives and, thus, of sensitivities of observables to continuous parameters. If the parameter $p(x)$ experiences a variation $\delta p(x)$ and corresponding variation of the observable R can be represented in the form of Eq. 11

$$\delta_p R = \int_{Dx} K_p(x) \delta p(x) dx \quad (17)$$

then sensitivity $\delta R/\delta p(x)$ is the kernel of this linear integral expression

$$\frac{\delta R}{\delta p(x)} \equiv K_p(x) \quad (18)$$

Using known solution Eq. 3, we can directly obtain sensitivities of observable in the above demo forward model Eq. 2 with respect to model parameters $a(t)$ and X_0 . Sensitivity to the discrete parameter X_0 is obtained as a partial derivative:

$$\frac{\partial R_1}{\partial X_0} = -\left(A(t_1) + (X_0)^{-1}\right)^{-2} \cdot (X_0)^{-2} = \left(\frac{R}{X_0}\right)^2 \quad (19)$$

Sensitivity to the continuous parameter $a(t)$ is obtained using the definition of the variational derivative Eqs. 11 and 12. We have

$$\delta_a R = -\left(A(t) + (X_0)^{-1}\right)^{-2} \int_{t_0}^{t_1} \delta a(t) dt = -R^2 \int_{t_0}^{t_1} \delta a(t) dt$$

Then

$$\frac{\delta R}{\delta a(t)} = -R^2 \quad (20)$$

Sensitivity analysis: computation of sensitivities of observables with respect to model parameters

Finite-difference approach

This approach is based on using differences between values of observables $R = M[X]$ computed from the solution X of the *baseline* (non-perturbed) forward problem $N[X] = S$ and values of observables $\tilde{R}_p = M[\tilde{X}_p]$ computed from the solution $\tilde{X}_p$ of the forward problem $\tilde{N}_p[X] = \tilde{S}_p$ with the operator and right-hand term perturbed due to perturbations $\tilde{p} = p + \Delta p$ of the retrieval parameter. Both components of the forward model, $\tilde{N}_p[X] = \tilde{S}_p$, and $\tilde{R}_p = M[\tilde{X}_p]$ are run separately for each discrete retrieval parameter and for each gridpoint of each continuous parameter. The matrix of sensitivities $K = \partial R / \partial p$ is approximated as

$$K = \frac{\partial R}{\partial p} \approx \frac{\tilde{R}_p - R}{\tilde{p} - p}$$

No analytic work is required here, but computer time, as compared to a single run of the forward model, increases in a direct proportion to the number of (gridpoints of) model parameters of interest.

Linearization approach

In this approach, the forward model Eq. 1 has to be linearized assuming that all model parameters of interest experience infinitesimally small perturbations. The resulting linearized forward problem has the form

$$L\delta X = \delta S - \delta N[X] \quad (21)$$

where the linear operator L represents a linearization of the operator N around the baseline solution of the forward problem X .

Note that only the right-hand term of the linearized forward problem Eq. 21 depends on variations of model parameters; the operator of the linearized forward problem L remains the same. This provides substantial savings of computer time.

After the linearized forward problem is formulated, it is solved for sensitivities of the forward solution $X(x)$ to model parameters: discrete p_j and continuous $p(x')$:

$$L \frac{\partial X}{\partial p_j} = \frac{\partial S}{\partial p_j} - \frac{\partial N[X]}{\partial p_j}, \text{ and } L \frac{\delta X}{\delta p(x')} = \frac{\delta S}{\delta p(x')} - \frac{\delta N[X]}{\delta p(x')}$$

Recalling that both N and S depend on continuous parameters as functions, and using the property Eq. 16, the linearized forward problem for sensitivities of the forward solution to continuous model parameters can be rewritten as

$$L \frac{\delta X}{\delta p(x')} = \delta(x' - x) \left(\frac{\partial S}{\partial p(x)} - \frac{\partial N[X]}{\partial p(x)} \right) \quad (22)$$

Further on, the instrument model Eq. 5 is linearized with respect to the forward solution X , resulting into a linear functional, which is written in the form of an inner product

$$\delta R = (W, \delta X) \quad (23)$$

This yields resulting expressions for sensitivities of observables to discrete and continuous parameters:

$$\frac{\partial R}{\partial p_j} = \left(W, \frac{\partial X}{\partial p_j} \right), \quad \frac{\delta R}{\delta p(x')} = \left(W, \frac{\delta X}{\delta p(x')} \right) \quad (24)$$

As an example, consider the linearization of the demo forward problem Eq. 2:

$$\begin{cases} \left(\frac{d}{dt} + 2a(t)X(t) \right) \delta X(t) = -X^2(t) \delta a(t) \\ \delta X(t_0) = \delta X_0 \end{cases}$$

Here we have

$$\begin{aligned} L\delta X &= \left(\frac{d}{dt} + 2a(t)X(t) + \delta(t - t_0) \right) \delta X(t), \\ \delta S(t) &= \delta(t - t_0) \delta X_0, \quad \delta N[X] = X^2(t) \delta a(t) \end{aligned} \quad (25)$$

We obtain sensitivities to parameters X_0 and $a(t)$ using known analytic solutions of this problem.

For X_0 , corresponding problem has the form

$$\begin{cases} \left(\frac{d}{dt} + 2a(t)X(t) \right)_{\delta X_0} = X(t) = 0 \\ \delta_{X_0} X(t_0) = \delta X_0 \end{cases}$$

Comparing its solution

$$\delta_{X_0} X(t) = \delta X_0 \exp \left(-2 \int_{t_0}^t a(t') X(t') dt' \right)$$

with definition Eq. 10, we have

$$\frac{\partial X(t)}{\partial X_0} = \exp \left(-2 \int_{t_0}^t a(t') X(t') dt' \right)$$

Using $A(t)$, a primitive function of $a(t)$ defined by Eq. 4, and transforming

$$\begin{aligned} \int_{t_0}^t a(t') X(t') dt' &= \int_{t_0}^t X(t') dA(t') \\ &= \ln \left[A(t') + (X_0)^{-1} \right] \Big|_{t_0}^t = \ln \left(\frac{X_0 A(t) + 1}{X_0 A(t_0) + 1} \right) \\ &= \ln \left(\frac{X_0}{X(t)} \right) \end{aligned}$$

yield

$$\frac{\partial X(t_1)}{\partial X_0} = \left(\frac{X(t_1)}{X_0} \right)^2$$

Thus

$$\frac{\partial R}{\partial X_0} = \left(\frac{R}{X_0} \right)^2 \quad (26)$$

in accordance with Eq. 19 obtained above using direct linearization.

For $a(t)$, the solution of the corresponding problem

$$\left(\frac{d}{dt} + 2a(t)X(t) \right) \delta_a X(t) = -X^2(t) \delta a(t), \delta_a X(t_0) = 0$$

has the form

$$\delta_a X(t) = - \int_{t_0}^t dt' \delta a(t') X^2(t') \exp \left(-2 \int_{t_0}^t a(t'') X(t'') dt'' \right)$$

Using $A(t)$, Eq. 4 and transforming

$$\begin{aligned} \int_{t'}^t a(t'') X(t'') dt &= \int_{t'}^t X(t'') dA(t'') \\ &= \ln [A(t'') + (X_0^{-1})] \Big|_{t'}^t = \ln \left(\frac{X_0 A(t) + 1}{X_0 A(t') + 1} \right) = \ln \left(\frac{X(t')}{X(t)} \right) \end{aligned}$$

yields the solution $\delta_a X(t)$ in the form suitable for direct computation of the sensitivity $\delta X(t)/\delta a(t')$:

$$\delta_a X(t) = -X^2(t) \int_{t_0}^t dt' \delta a(t'), \text{ and } \frac{\delta X(t)}{\delta a(t')} = -X^2(t)$$

Then

$$\frac{\delta X(t_1)}{\delta a(t)} = -X^2(t_1)$$

and

$$\frac{\delta R}{\delta a(t)} = -R^2 \quad (27)$$

in accordance with Eq. 20 obtained above using direct linearization.

Adjoint approach

In this approach, the operator L and right-hand term $\delta S - \delta N[X]$ of the linearized forward problem Eq. 21, along with the observables weighting function W of the linearized instrument model Eq. 23, are used in an alternative way involving the operator L^* , which is adjoint to L . This approach is more efficient when the number of parameters to be retrieved (counted by separate gridpoint

values for continuous parameters) exceeds the number of observables.

Rewriting for brevity the linearized forward model Eq. 21 as

$$LX' = S' \quad (28)$$

where $S' = \delta S - \delta N[X]$ and rewriting the linearized instrument model Eq. 23 as

$$R' = (W, X') \quad (29)$$

this approach can be outlined as follows. The adjoint operator L^* is derived from the requirement that the identity

$$(g, Lf) = (L^*g, f) \quad (30)$$

be satisfied for an arbitrary pair of functions f and g in the domain of L . Then, the solution X^* of the *adjoint problem*

$$L^*X^* = W \quad (31)$$

provides an alternative way to compute the linearized observables:

$$R' = (X^*, S') \quad (32)$$

This can be demonstrated by multiplying the adjoint problem by X' and the linearized forward problem by X^* and comparing the left and right sides of the resulting equalities:

$$(L^*X^*, X') = (W, X'), (X^*, LX') = (X^*, S')$$

Since the left-hand terms (L^*X^*, X') and (X^*, LX') are equal by definition of the adjoint operator, the right-hand terms (W, X') and (X^*, S') are also equal. Since $(W, X') = R'$, then $R' = (X^*, S')$.

Now, returning back from abbreviated Eq. 28 to Eq. 21 and replacing in Eq. 32 $R' \rightarrow \delta R$ and $S' \rightarrow \delta S - \delta N[X]$, we obtain a direct expression of the variation of the observables through variations of the operator and right-hand term of the forward problem:

$$\delta R = (X^*, \delta S - \delta N[X]) \quad (33)$$

This yields expressions for sensitivities of observables to discrete and continuous parameters in the form

$$\begin{aligned} \frac{\delta R}{\partial p_j} &= \left(X^*, \frac{\partial S}{\partial p_j} - \frac{\partial N}{\partial p_j} X \right), \text{ and } \frac{\delta R}{\delta p(x')} \\ &= \left(X^*, \frac{\delta S}{\delta p(x')} - \frac{\delta N}{\delta p(x')} X \right) \end{aligned} \quad (34)$$

As an example, consider a matrix forward problem

$$\begin{cases} \frac{d\mathbf{X}}{dt} + \mathbf{a}(t)\mathbf{X}(t) = \mathbf{b}(t) \\ \mathbf{X}(t_0) = \mathbf{X}_0 \end{cases} \quad (35)$$

where $\mathbf{a}(t)$ is a $n \times n$ -matrix and $\mathbf{X}(t)$, $\mathbf{b}(t)$, and $\mathbf{X}_0$ are n -vectors. The forward operator has the form

$$\mathbf{L}\mathbf{X} = \left(\frac{d}{dt} + \mathbf{a}(t) \right) \mathbf{X}(t) + \delta(t - t_0) \mathbf{X}(t) \quad (36)$$

To derive the operator adjoint to $\mathbf{L}$, we write down the left side of the identity Eq. 30 and transform it to the right side of this identity. For the left side of Eq. 30, we have

$$(\mathbf{X}^*, \mathbf{L}\mathbf{X}) = \int_{t_0}^{t_1} \mathbf{X}^{*T}(t) \left(\frac{d\mathbf{X}}{dt} + \mathbf{a}(t)\mathbf{X}(t) + \delta(t - t_0)\mathbf{X}(t) \right) dt$$

Performing integration by parts and canceling terms with opposite signs

$$\begin{aligned} & \int_{t_0}^{t_1} \mathbf{X}^{*T}(t) \frac{d\mathbf{X}}{dt} dt + \int_{t_0}^{t_1} \delta(t - t_0) \mathbf{X}(t) \mathbf{X}^{*T}(t) dt = \\ & - \int_{t_0}^{t_1} \frac{d\mathbf{X}^{*T}}{dt} \mathbf{X}(t) dt + \int_{t_0}^{t_1} \delta(t_1 - t) \mathbf{X}^{*T}(t) \mathbf{X}(t) dt \end{aligned}$$

we rewrite $(\mathbf{X}^*, \mathbf{L}\mathbf{X})$ in the form of the right side of Eq. 30:

$$\begin{aligned} & \int_{t_0}^{t_1} \left(-\frac{d\mathbf{X}^*}{dt} + \mathbf{a}^T(t)\mathbf{X}^*(t) + \delta(t_1 - t)\mathbf{X}^*(t) \right)^T \mathbf{X}(t) dt \\ & = (\mathbf{L}^* \mathbf{X}^*, \mathbf{X}) \end{aligned}$$

This yields the expression for the operator $\mathbf{L}^*$ adjoint to operator $\mathbf{L}^*$, Eq. 36:

$$\mathbf{L}^* \mathbf{X}^* = \left(-\frac{d}{dt} + \mathbf{a}^T(t) \right) \mathbf{X}^*(t) + \delta(t_1 - t) \mathbf{X}^*(t) \quad (37)$$

To formulate the adjoint problem in the form of Eq. 31, we assume observables as an m -vector $\mathbf{R}$. This yields the linearized instrument model in the form

$$\mathbf{R} = (\mathbf{W}, \mathbf{X}) = \int_{t_0}^{t_1} \mathbf{W}^T(t) \mathbf{X}(t) dt \quad (38)$$

with observables weighting function $\mathbf{W}(t)$ being an $m \times n$ -matrix. Assuming the vector $\mathbf{R} = \mathbf{W}_0 \mathbf{X}(t_1)$ is to be computed using a constant matrix $\mathbf{W}_0$ applied to the forward solution $X(t)$ at $t = t_1$, we have $\mathbf{W}(t) = \delta(t_1 - t) \mathbf{W}_0$. Corresponding adjoint problem has the form

$$\begin{cases} -\frac{d\mathbf{X}^*}{dt} + \mathbf{a}^T(t)\mathbf{X}^*(t) = 0 \\ \mathbf{X}^*(t_1) = \mathbf{W}_0^T \end{cases} \quad (39)$$

As an illustration, consider the nonlinear demo forward model Eqs. 2 and 7. Repeating above derivations for the operator of corresponding linearized forward problem, Eq. 25, we obtain

$$L^* X^* = \left(-\frac{d}{dt} + 2a(t)X^*(t) + \delta(t - t_1) \right) X^*(t) \quad (40)$$

Thus, corresponding adjoint problem has the form

$$\begin{cases} -\frac{dX^*}{dt} + 2a(t)X(t)X^*(t) = 0 \\ X^*(t_1) = 1 \end{cases} \quad (41)$$

Its solution (note that integration proceeds backward):

$$X^*(t) = \exp \left(-2 \int_t^{t_1} a(t') X(t') dt' \right)$$

To obtain sensitivities to parameters, we will use Eq. 33. For the sensitivity to the discrete parameter X_0 , we have

$$\begin{aligned} \delta_{X_0} R &= (X^*, \delta_{X_0}(S)) = \int_{t_0}^{t_1} X^*(t) \delta(t - t_0) \delta X_0 dt \\ &= X^*(t_0) \delta X_0 = \exp \left(-2 \int_{t_0}^{t_1} a(t') X(t') dt' \right) \delta X_0 \\ &= \left(\frac{R}{X_0} \right)^2 \delta X_0 \end{aligned}$$

Thus

$$\frac{\partial R}{\partial X_0} = \left(\frac{R}{X_0} \right)^2 \quad (42)$$

in accordance with Eqs. 19 and 26 obtained above using direct linearization and the linearization approach.

For the sensitivity to the continuous parameter $a(t)$, we have

$$\delta_a R = (X^*, -(\delta_a N)[X])$$

Rewriting $X^*(t)$

$$\begin{aligned} X^*(t) &= \exp \left(-2 \int_t^{t_1} a(t') X(t') dt' \right) \\ &= \exp \left[-2 \left(\int_{t_0}^{t_1} a(t') X(t') dt' - \int_{t_0}^t a(t') X(t') dt' \right) \right] \\ &= \frac{\exp \left(-2 \int_{t_0}^{t_1} a(t') X(t') dt' \right)}{\exp \left(-2 \int_{t_0}^t a(t') X(t') dt' \right)} = \frac{(X(t_1)/X_0)^2}{(X(t)/X_0)^2} = \frac{R^2}{X^2(t)} \end{aligned}$$

we have

$$\begin{aligned}\delta_a R &= (X^*, -(\delta_a N)[X]) = - \int_{t_0}^{t_1} X^*(t) X^2(t) \delta_p a(t) dt \\ &= -R^2 \int_{t_0}^{t_1} \delta a(t) dt\end{aligned}$$

Thus

$$\frac{\delta R}{\delta a(t)} = -R^2 \quad (43)$$

in accordance with Eqs. 20 and 27 obtained above using direct linearization and the linearization approach.

Summary

Forward modeling is a necessary component of geophysical retrieval algorithms. It includes the forward problem (the quantitative description of the subject of the geophysical retrieval itself) and the instrument model (the quantitative description of the procedure of measurements). In the most general case, the forward problem is represented by a system of differential equations with initial and/or boundary conditions, which, in general, can be solved only numerically. On the other hand, the instrument model is represented by an analytic expression, which converts the solution of the forward problem into observables, which simulate measured quantities used in geophysical retrievals.

Together, the forward model serves two functions. Besides simulated observables, it provides sensitivities of these observables with respect to the model parameters intended to be retrieved. This can be done in three different ways depending on the preferences of the researcher and on the relation between numbers of observables and model parameters to be retrieved. The finite-difference approach is most straightforward, but also least computer efficient at the same time. The linearization approach is more sophisticated, and it is preferable when the number of parameters to be retrieved is less than the number of observables. The adjoint approach is the most sophisticated and is preferable when parameters to be retrieved outnumber the observables, like in the retrievals of atmospheric profiles in atmospheric remote sensing.

A substantial amount of literature exists on forward modeling and sensitivity analysis (although under various names) in various areas of remote sensing, and the reader is encouraged, once he/she gets a big picture, to do independent search for this literature and to surf the Internet for this purpose. The references below will help in implementation of practical algorithms.

GEOPHYSICAL RETRIEVAL, INVERSE PROBLEMS IN REMOTE SENSING

Eugene Ustinov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA, USA

Definition

Forward model. Quantitative tool for simulation of observables for a given set of model parameters.

Forward problem. System of differential equations with initial and/or boundary conditions, the solution of which, the *forward solution*, is used for simulation of observables.

Forward solution. Solution of the *forward problem*.

Instrument model. Quantitative procedure for evaluation of observables from the *forward solution*, which models the characteristics of the instrument and the procedure for measurements.

Inverse problem. Mathematical problem, usually in the form of a matrix equation, the solution of which, the *inverse solution*, represents an estimate of the *state vector*.

Model parameters. Parameters of the forward problem contained in its differential equations and initial and/or boundary conditions.

Observables. Output parameters of the *forward model*, which simulate the quantities measured in the geophysical retrieval.

Sensitivities. Partial or variational derivatives of *observables* with respect to *model parameters*.

State vector. Subset of the set of model parameters, which is intended to be retrieved.

Introduction

In contrast to *forward modeling*, which proceeds from assumed values of model parameters of the subject of study to simulated observables, the input in inverse modeling consists of measured observables, and the output consists of retrieved model parameters. Also, in contrast to forward modeling, where modeling of observables includes two

major components – *forward problem* (conversion of model parameters into the *forward solution*) and *instrument model* (conversion of the forward solution into simulated observables) – inverse modeling consists of only one major component, *inverse problem*, which converts the measured observables into estimates of the *state vector*, a subset of model parameters subject to the retrieval.

The value of any physical measurement – direct, like in situ measurements, or indirect, like in geophysical retrievals – has to be associated with its uncertainty, measurement error. Thus, it is highly desirable to retrieve the values of model parameters along with their *retrieval errors* (aka error bars). The existing methods of solution of the inverse problem deliver the solution along with its retrieval errors derived from errors of measurements driven by the instrument design.

Formulation and information analysis of the inverse problem

As stated in the accompanying article “*Forward Modeling*,” the quantitative relation between model parameters $\mathbf{p}$, and simulated observables $\mathbf{R}$ is, in general, nonlinear. The inverse problem is formulated, essentially, as inversion of this relation. Using high-level notations, we have:

$$\mathbf{F}(\mathbf{p}) = \mathbf{R} \quad (1)$$

It is assumed that all continuous model parameters are represented by their values on suitable grids of arguments and, correspondingly, $\mathbf{F}$ is a vector function of a vector argument.

The necessary premise for the formulation of the inverse problem is the availability of a computational procedure, which, for a given set of n model parameters described by a vector $\mathbf{p}$, provides a capability to compute a set of m observables described by a vector $\mathbf{R}$ along with their partial derivatives $\partial\mathbf{R}/\partial\mathbf{p}$ treated as a single $m \times n$ matrix of sensitivities $\mathbf{K}$. Another premise, which is necessary for the error analysis of the resulting inverse problem, as well as for its solution afterward, is knowledge of measurement errors – uncertainties of measured observables described by an m – vector $\boldsymbol{\epsilon}$. Computation of the corresponding covariance matrix is a necessary attribute of the algorithm of solution of the inverse problems in geophysical retrievals.

Differences between measured and simulated observables are commonly referred to as *residuals*. The nonlinear inverse problem is solved iteratively, and at each iteration, the solution of the corresponding linearized inverse problem yields corrections to the current approximation of the set of model parameters. These corrections are commonly referred to as *increments*.

The nonlinear inverse problem is solved iteratively. The corresponding linearized inverse problem in high-level notations has the form:

$$\mathbf{K}\mathbf{x} = \mathbf{y} \quad (2)$$

where $\mathbf{y} = \mathbf{R}_{obs} - \mathbf{R}$ is the m – vector of residuals and $\mathbf{x} = \mathbf{p}_{next} - \mathbf{p}$ is the n – vector of increments.

Based on the sensitivity matrix $\mathbf{K}$, a preliminary information analysis of the inverse problem can be conducted. In general, not all elements of the measurement set are independent from each other, and, as a result, the number of linearly independent rows of $\mathbf{K}$ may be less than the total number of the rows. The number $r \leq m$ of linearly independent rows is referred to as the *rank* of the matrix $\mathbf{K}$.

Rank of matrix $\mathbf{K}$ can be determined using a technique called singular value decomposition. An eigenvalue problem is considered in the form:

$$\begin{pmatrix} \mathbf{0} & \mathbf{K} \\ \mathbf{K}^T & \mathbf{0} \end{pmatrix} \begin{pmatrix} \mathbf{u} \\ \mathbf{v} \end{pmatrix} = \lambda \begin{pmatrix} \mathbf{u} \\ \mathbf{v} \end{pmatrix} \text{ or, in explicit form :} \\ \mathbf{K}\mathbf{v} = \lambda\mathbf{u} \\ \mathbf{K}^T\mathbf{u} = \lambda\mathbf{v} \quad (3)$$

Here $\mathbf{u}$ is an m – vector in the space of measurement vectors and $\mathbf{v}$ is an n – vector in the space of state vectors. This problem can be rewritten in the form of two eigenvalue problems for matrices $\mathbf{K}^T\mathbf{K}(n \times n)$ and $\mathbf{K}\mathbf{K}^T(m \times m)$:

$$\mathbf{K}^T\mathbf{K}\mathbf{v} = \lambda^2\mathbf{v} \quad (4)$$

$$\mathbf{K}\mathbf{K}^T\mathbf{u} = \lambda^2\mathbf{u} \quad (5)$$

which are solved by standard methods. The numbers of resulting nonzero eigenvalues of the matrices $\mathbf{K}^T\mathbf{K}$ and $\mathbf{K}\mathbf{K}^T$ coincide and yield the rank p of the matrix $\mathbf{K}$.

Number of degrees of freedom (DOF) for signal d_s is another quantitative measure of quality of the measurements selected for the retrieval. It indicates how many independent quantities can be measured. In general, it is not an integer number:

$$d_s = \text{tr} \left(\Lambda^2 (\Lambda^2 + \mathbf{I}_m)^{-1} \right) = \sum_{i=1}^m \frac{\lambda_i^2}{\lambda_i^2 + 1} \quad (6)$$

An indicator complementary to d_s is the number of degrees of freedom for noise d_n :

$$d_n = \text{tr} \left((\Lambda^2 + \mathbf{I}_m)^{-1} \right) = \sum_{i=1}^m \frac{1}{\lambda_i^2 + 1} \quad (7)$$

Shannon information content H of measurements used in retrievals with a given matrix $\mathbf{K}$ can be estimated assuming Gaussian noise:

$$H = \frac{1}{2} \sum_{i=1}^m \ln(1 + \lambda_i^2) \quad (8)$$

Solution of Inverse Problems

Unlike solution of forward problems, which, in principle, can be accomplished with any numerical accuracy, solution of inverse problems is associated with inherent uncertainty, for two general reasons: presence of measurement errors, and the indirect, inference-like nature of the process of retrieval, which is implemented by solution of the inverse problem.

The presence of measurement errors forces to consider the residuals vector $\mathbf{y}$ as a random quantity. It is customary to replace $\mathbf{y} \rightarrow \mathbf{y} + \boldsymbol{\varepsilon}$, where the vector of measurement errors $\boldsymbol{\varepsilon}$ is assumed to obey the Gaussian distribution with an average (mathematical expectation) $\bar{\boldsymbol{\varepsilon}} = 0$ and a covariance matrix $\mathbf{C}_y$. The corresponding *probability distribution function* (PDF) has the form:

$$P(\boldsymbol{\varepsilon}) \propto \exp\left(-\frac{1}{2} \boldsymbol{\varepsilon}^T \mathbf{C}_y^{-1} \boldsymbol{\varepsilon}\right) \quad (9)$$

where the symbol “ $\propto$ ” means proportionality. In the case of non-correlating measurement errors $s_i (i = 1, \dots, m)$ Eq. 9 can be rewritten as

$$P(\boldsymbol{\varepsilon}) \propto \exp\left(-\frac{1}{2} \sum_{i=1}^m \frac{\varepsilon_i^2}{s_i^2}\right) \quad (10)$$

With measurement errors included explicitly, the inverse problem Eq. 2 takes the form

$$\mathbf{K}\mathbf{x} = \mathbf{y} + \boldsymbol{\varepsilon} \quad (11)$$

where the vector $\mathbf{x}$ is treated as a random quantity, which also obeys the Gaussian distribution with the PDF:

$$P(\mathbf{x}) \propto \exp\left(-\frac{1}{2} (\mathbf{x} - \bar{\mathbf{x}})^T \mathbf{C}_x^{-1} (\mathbf{x} - \bar{\mathbf{x}})\right) \quad (12)$$

The solution of the inverse problem Eq. 2 is sought as the average $\bar{\mathbf{x}}$ of this distribution, whereas the covariance matrix $\mathbf{C}_x$ describes uncertainty (retrieval errors) of this solution.

By definition of the covariance matrix, $\mathbf{C}_x$ is symmetric, i.e., $\mathbf{C}_x = \mathbf{C}_x^T$, and $\mathbf{C}_x^{-1} = (\mathbf{C}_x^{-1})^T$. Then, the PDF Eq. 12 can be transformed as

$$P(\mathbf{x}) \propto \exp\left(-\frac{1}{2} \mathbf{x}^T \mathbf{B} \mathbf{x} + \mathbf{b}^T \mathbf{x}\right) \quad (13)$$

where

$$\mathbf{B} = \mathbf{C}_x^{-1} \quad (14)$$

and

$$\mathbf{b} = \mathbf{B} \bar{\mathbf{x}} \quad (15)$$

On the other hand, the PDF $P(\mathbf{x})$ can be derived from the PDF $P(\boldsymbol{\varepsilon})$ Eq. 9 by the substitution $\boldsymbol{\varepsilon} = \mathbf{K}\mathbf{x} - \mathbf{y}$. Essentially, this is an *a posteriori* PDF for the random quantity $\mathbf{x}$ with quantity $\mathbf{y}$ known:

$$P(\mathbf{x}|\mathbf{y}) \propto \exp\left(-\frac{1}{2} (\mathbf{K}\mathbf{x} - \mathbf{y})^T \mathbf{C}_y^{-1} (\mathbf{K}\mathbf{x} - \mathbf{y})\right) \quad (16)$$

We have:

$$\begin{aligned} & (\mathbf{K}\mathbf{x} - \mathbf{y})^T \mathbf{C}_y^{-1} (\mathbf{K}\mathbf{x} - \mathbf{y}) \\ &= (\mathbf{K}\mathbf{x})^T \mathbf{C}_y^{-1} \mathbf{K}\mathbf{x} - (\mathbf{K}\mathbf{x})^T \mathbf{C}_y^{-1} \mathbf{y} - \mathbf{y}^T \mathbf{C}_y^{-1} \mathbf{K}\mathbf{x} + \mathbf{y}^T \mathbf{y} \end{aligned} \quad (17)$$

Note that all terms in Eq. 17 are scalars, and thus are equal to themselves transposed. In particular

$$\mathbf{y}^T \mathbf{C}_y^{-1} \mathbf{K}\mathbf{x} = (\mathbf{K}\mathbf{x})^T \mathbf{C}_y^{-1} \mathbf{y}$$

Observing also that the term $\mathbf{y}^T \mathbf{y}$ in Eq. 17 does not depend on $\mathbf{x}$ we can rewrite Eq. 16 as:

$$P(\mathbf{x}|\mathbf{y}) \propto \exp\left(-\frac{1}{2} \mathbf{x}^T \mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{K} \mathbf{x} + \mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{y}\right) \quad (18)$$

Comparing Eq. 18 with the general form of PDF Eq. 13, we obtain:

$$\mathbf{B} = \mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{K} \quad (19)$$

and

$$\mathbf{b} = \mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{y} \quad (20)$$

Comparison with the equality Eq. 15 yields a matrix equation for the solution $\bar{\mathbf{x}}$ of the inverse problem Eq. 2:

$$\mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{K} \bar{\mathbf{x}} = \mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{y} \quad (21)$$

along with the expression for the covariance matrix of this solution:

$$\mathbf{C}_x = \left(\mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{K}\right)^{-1} \quad (22)$$

In the particular case of non-correlated equal measurement errors, when $s_i \equiv s$, the matrix equation Eq. 21 and expression for the covariance matrix of its solution Eq. 22 reduce to:

$$\mathbf{K}^T \mathbf{K} \bar{\mathbf{x}} = \mathbf{K}^T \mathbf{y} \quad (23)$$

and

$$\mathbf{C}_x = s^2 (\mathbf{K}^T \mathbf{K})^{-1} \quad (24)$$

If the PDF of $\mathbf{x}$ can be sufficiently constrained based on some additional, *a priori* information, then the number of

measurements m can be less than the dimension n of $\mathbf{x}$. This is the case, e.g., in atmospheric remote sensing, when information about correlation between values of the atmospheric parameter to be retrieved can be invoked in the form of a covariance matrix

$$\mathbf{C}_{\mathbf{x},a} = \overline{\mathbf{x}\mathbf{x}^T} \quad (25)$$

Then the a priori PDF of $\mathbf{x}$ can be represented in the form of the corresponding Gaussian distribution

$$P_a(\mathbf{x}) \propto \exp\left(-\frac{1}{2} \mathbf{x}^T \mathbf{C}_{\mathbf{x},a}^{-1} \mathbf{x}\right) \quad (26)$$

and the resulting constrained PDF is a product of PDFs Eqs. 18 and 26:

$$P_c(\mathbf{x}|\mathbf{y}) = P(\mathbf{x}|\mathbf{y}) \cdot P_a(\mathbf{x}) \\ \propto \exp\left(-\frac{1}{2} \mathbf{x}^T (\mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{K} + \mathbf{C}_{\mathbf{x},a}^{-1}) \mathbf{x} + \mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{y}\right) \quad (27)$$

Correspondingly, the matrix equation for the solution $\bar{\mathbf{x}}$ of the *regularized* inverse problem Eq. 2 and expression for the covariance matrix $\mathbf{C}_x$ of this solution, respectively, take the form:

$$(\mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{K} + \mathbf{C}_{\mathbf{x},a}^{-1}) \bar{\mathbf{x}} = \mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{y} \quad (28)$$

$$\mathbf{C}_x = (\mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{K} + \mathbf{C}_{\mathbf{x},a}^{-1})^{-1} \quad (29)$$

In practice, the number of measurements m in atmospheric remote sensing can be larger, and even much larger than n , e.g., in retrievals from data of high-resolution spectral measurements with the Tropospheric Emissions Spectrometer (TES) flown on the Aura spacecraft. But the rank r of the corresponding sensitivity matrix $\mathbf{K}(m \times n)$ is of the order of the number of atmospheric scale heights over the altitude range covered by retrievals. Of course, the number of necessary grid points n is substantially larger, and, thus, invoking of a priori information is necessary.

Recall that in general the inverse problem $\mathbf{F}(\mathbf{p}) = \mathbf{R}$ is nonlinear and it has to be solved using the linearized inverse problem $\mathbf{K}\mathbf{x} = \mathbf{y}$. If the first guess of the state vector $\mathbf{p}_0$ is too far from the solution, then a straightforward application of the above approach at each iteration may not converge to the solution. A more robust approach named Levenberg–Marquardt method, which has a long history of development (see Rodgers (2000) for a review), makes it possible to cope with this difficulty. At each iteration, the size of the step $\bar{\mathbf{x}}$ is regulated by introducing an additional matrix term proportional to a scalar γ , which is chosen based on some semiempirical rules. If no regularization is necessary, this matrix term is $\gamma\mathbf{D}$, where $\mathbf{D}$ is a diagonal scaling matrix with elements corresponding to magnitudes and dimensions of the elements of the state vector $\mathbf{p}$. If the vector $\mathbf{p}$ consists of elements of same magnitudes and dimensions, then $\mathbf{D}$ reduces to the identity matrix $\mathbf{I}$. If regularization is

necessary, Rodgers (2000) suggests this term in the form $\gamma\mathbf{C}_{\mathbf{x},a}^{-1}$. Thus, the step $\bar{\mathbf{x}}$ is sought as a solution of the above matrix equations modified accordingly:

$$(\mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{K} + \gamma\mathbf{D}) \bar{\mathbf{x}} = \mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{y} \quad (30)$$

or

$$(\mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{K} + (1 + \gamma)\mathbf{C}_{\mathbf{x},a}^{-1}) \bar{\mathbf{x}} = \mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{y} \quad (31)$$

Error analysis of inverse problems

The covariance matrix $\mathbf{C}_x$ provides a straightforward way for estimations of the retrieval errors (error bars) of retrieved profiles defined as variances derived from the covariance matrix

$$\sigma_j = \sqrt{(x_j - \bar{x}_j)^2} = \sqrt{(\mathbf{C}_x)_{jj}}, \quad (j = 1, \dots, n) \quad (32)$$

When additional information about the solution in the form of the a priori covariance matrix $\mathbf{C}_{\mathbf{x},a}$ is used, then additional, *smoothing* errors emerge. Whereas error bars represent uncertainties of retrieved values, the smoothing errors represent uncertainties of benchmarking of retrieved values, e.g., retrieved atmospheric profiles, to specific reference arguments, e.g., altitude in the atmosphere. This smoothing error is represented by the $n \times n$ matrix $\mathbf{A} = \partial\bar{\mathbf{x}}/\partial\mathbf{x}$ called the *averaging kernel*. Using the substitution $\mathbf{y} = \mathbf{K}\mathbf{x}$ in the right-hand term of the regularized inverse problem in Eq. 28, and solving it for $\bar{\mathbf{x}}$, we have:

$$\bar{\mathbf{x}} = (\mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{K} + \mathbf{C}_{\mathbf{x},a}^{-1})^{-1} \mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{K} \mathbf{x}$$

Thus the averaging kernel $\mathbf{A}$ has the form:

$$\mathbf{A} = (\mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{K} + \mathbf{C}_{\mathbf{x},a}^{-1})^{-1} \mathbf{K}^T \mathbf{C}_y^{-1} \mathbf{K} \quad (33)$$

It should be emphasized that the accuracy of estimation of the smoothing error represented by the matrix $\mathbf{A}$ depends on the accuracy of the knowledge of a priori covariance matrix $\mathbf{C}_{\mathbf{x},a}$. On the other hand, if the solution does not need to be constrained, then a priori PDF $P(\mathbf{x}) \propto 1$ and correspondingly $\mathbf{C}_{\mathbf{x},a}^{-1} = 0$, and the averaging kernel $\mathbf{A}$ reduces to the $n \times n$ identity matrix $\mathbf{I}_n$.

Finally, retrieval errors may be associated with uncertainties in parameters of the forward model, which are not being retrieved and have to be assumed based on some independent information. General analysis of associated uncertainties is given in the monograph of Clive Rodgers (2000).

Summary

Formulation of the inverse problem, analysis of its information content, choice of the method of its solution, and analysis of resulting retrieval errors represent main phases of development of the inversion algorithm in

geophysical retrievals. The key premise is availability of the adequate forward model, which, for a given set of model parameters, provides accurate values of simulated observables along with the matrix of sensitivities of observables with respect to elements of the state vector. This makes it possible to formulate the linearized inverse problem. If this problem is ill posed, then the algorithm of its solution involves regularization using some a priori information about this solution. The solution is sought as an average over a probability distribution, which is driven by the probability distribution of measurement errors around the measured observables and by the matrix of sensitivities provided by the forward model. The variance of the probability distribution of the solution provides the estimate of retrieval errors. If necessary, this estimate needs to be complemented by estimates of errors due to uncertainties of the model parameters outside the state vector and due to the approximate nature of the forward model.

There is a vast amount of literature describing formulation and solution of inverse problems in geophysical retrievals. The reader is encouraged, once he/she gets a big picture, to do an independent search for this literature and to surf the Internet for this purpose. The monograph by Clive Rodgers (2000) is a rich source of information on formulation and solution of inverse problems in atmospheric remote sensing, which, as a rule, are ill-posed and need regularization. Two other monographs provide valuable information on various aspects of practical implementation of algorithms of solution of inverse problems.

GEOPHYSICAL RETRIEVAL, OVERVIEW

Eugene Ustinov
Jet Propulsion Laboratory, California Institute of
Technology, Pasadena, CA, USA

Definition

Forward model. Quantitative tool for simulation of *observables* for a given set of *model parameters*.

Forward problem. System of differential equations with initial and/or boundary conditions, solution of which, the *forward solution*, is used for simulation of *observables*.

Forward solution. Solution of the *forward problem*.

Instrument model. Quantitative procedure for evaluation of observables from the *forward solution*, which models the characteristics of the instrument and the procedure for measurements.

Inverse problem. Mathematical problem, usually in the form of a matrix equation, solution of which, the *inverse solution*, represents an estimate of the *state vector*.

Model parameters. Parameters of the forward problem contained in its differential equations and initial and/or boundary conditions.

Observables. Output parameters of the forward model, which simulate the quantities measured in the geophysical retrieval.

Sensitivities. Partial or variational derivatives of *observables* with respect to *model parameters*.

State vector. Subset of the set of model parameters, which is intended to be retrieved.

Introduction

Geophysical retrievals are indirect measurements. In contrast to direct measurements, where there is a direct relation between the measured quantity (e.g., length of the mercury column in the thermometer and inferred quantity – temperature), in geophysical retrievals, the quantities to infer (retrieve) are related to measured quantities via an intermediary, a *forward model*, which provides a cause-to-effect relation between quantities to infer (a subset of *model parameters* constituting the *state vector*) and measured quantities (*observables*). For example, in atmospheric remote sensing, the parameters of the atmosphere/surface system are retrieved using measurements of radiances measured at the top of the atmosphere. Thus, in the retrieval process, we proceed back, from the effect, i.e., observed radiances, to the cause – atmospheric and surface parameters – specific values of which result in specific values of the measured radiances, which are used for the retrieval.

To adequately describe the dependence of measured quantities on the model parameters, the forward model has to have two mandatory components. Its first component is the *forward problem* – the description of the subject of retrieval, based on known physics of it, usually, in the form of a system of differential equations with corresponding initial and/or boundary conditions. In the case considered above, the forward problem consists of the equation of radiative transfer (RT) with boundary conditions complemented by known dependencies of radiative parameters directly entering the RT equation and boundary conditions, such as the Planck function, on geophysical parameters of interest, such as atmospheric temperature. In high-level notation, the forward problem can be written in the form of an operator equation:

$$LX = S$$

where the operator L denotes all homogeneous operations on the solution X contained in the differential equations and initial and/or boundary conditions of the forward problem and the right-hand term S combines all nonhomogeneous right-hand terms of the equations and conditions.

The second component of the forward model is the *instrument model*. In the above case, this model consists of angular and spectral distributions of the instrument's response. Convolution of the solution of the forward problem with functions describing the instrument model provides observables, which simulate measured quantities. In high-level notation, the expression for observables can be written in the form of an inner product of the forward solution X with the function W describing the response of the instrument:

$$R = (W, X)$$

Besides observables, the forward model provides another entity – *sensitivities* of observables to the parameters to be retrieved. Essentially, sensitivities are derivatives of observables with respect to the model parameters to be retrieved. For example, in atmospheric remote sensing, temperature weighting functions are sensitivities of observed radiances with respect to temperature. Sensitivities computed along with observables provide premises necessary to solve the *inverse problem*. In contrast to the forward model, the input of the inverse problem is the set of measured observables, and its output is the set of retrieved model parameters providing the best fit of computed observables to measured observables. Solution of the inverse problem implements the aforementioned path from effect to cause. This circumstance is the key reason of complications associated with the solution of the inverse problems.

Forward model: forward problem and sensitivity analysis

Solution of the forward problem and computation of sensitivities constitute two major components of the algorithm implementing the forward model. There are many software packages available, which make implementation of the forward problem in the forward model to be rather a craft than a skill. On the other hand, computation of sensitivities can be implemented in a number of ways, depending on preferences of the algorithm developer.

The simplest but most computer-intensive approach to computation of sensitivities is termed the *finite-difference approach*. The forward model is run once to obtain the baseline solution for the given set of values of model parameters. Then, the parameters to be retrieved are varied one by one, gridpoint by gridpoint. For each such variation, the forward problem is run separately. Resulting variations of observables are divided by variations of parameters yielding the sensitivity matrix – a matrix of partial derivatives of observables with respect to the model parameters to be retrieved.

Two other approaches require some mathematical skills and additional computer programming. For their application, the forward problem and instrument model of the forward model need to be linearized around the baseline solution. The resulting *linearized forward problem* and *linearized instrument model* can be used in two ways, complementing each other, depending on the relation between the number of observables and the number of retrieval parameters.

The *linearization approach* is based on the linearized forward problem formulated for derivatives of the baseline solution with respect to retrieval parameters. The linearized instrument model is applied to obtained derivatives of the baseline solution to calculate partial derivatives of observables with respect to retrieval parameters. The key point is that only right-hand terms of equations (differential equations and initial and/or boundary conditions) in the linearized forward problem vary with the specific retrieval parameter. The left-hand operations on the derivatives of the solution are the same. This provides substantial savings as compared to the finite-difference approach. An illustrative analogy here is the solution of a system of linear algebraic equations for a number of cases where only right-hand inhomogeneous terms vary, but coefficients in the left-hand homogeneous terms remain the same.

The *adjoint approach* is also based on the use of the linearized forward problem and linearized instrument model, but in a different way. It requires more mathematical skills than the linearization approach, as well as additional computer programming. All left-hand operations in the linearized forward problem are combined into a linear operator of this problem. The corresponding adjoint operator is derived based on the definition of this operator. The adjoint problem is formulated using the obtained adjoint operator with the linearized instrument models for given observables as right-hand terms. It turns out that the corresponding *adjoint solution* provides a way to obtain sensitivities with respect to all model parameters at once. Similarly to the linearization approach, all left-hand operations in the adjoint problem are the same, and only right-hand terms vary with the specific observable.

Comparison of performance of the linearization and adjoint approaches is based, essentially, on the comparison of the number of observables with the number of retrievable parameters. It is important to point out here that in the case of continuous parameters, such as atmospheric parameters, the value at each gridpoint should be counted as a separate parameter. With this in mind, if the number of observables exceeds the number of retrievable parameters, then the linearization approach is more efficient. In the opposite case, the adjoint approach is more efficient. For example, in many cases of atmospheric remote sensing, the observables are spectral radiances: a single radiance or some number of them observed at different nadir angles. The retrieval parameters are atmospheric profiles, usually specified on a few tens of gridpoints in the atmosphere. Objectively, the adjoint approach is more efficient

here. But historically, the linearization approach is still dominating, apparently because it is easier to comprehend and implement.

In a few practical situations, the forward problems can be solved analytically. For example, this is the case for radiative transfer of thermal radiation in the non-scattering atmosphere, which may be a good approximation, especially in the microwave spectral region. Then, observed radiances are also available analytically, and corresponding expressions can be linearized to yield sensitivities to desired parameters to be retrieved. The equation of radiative transfer is linear per se, so no linearization is necessary. Application of the adjoint approach in this case results in the adjoint problem, which also can be solved analytically. Of course, resulting analytic expressions for sensitivities are identical to those obtained directly.

Inverse problems and their solution

As was pointed out in the Introduction, the forward models proceed from model parameters (cause) to observables (effect) in two steps. The first step is implemented by the forward problem, which yields a forward solution providing a quantitative description of the subject of retrieval, per se, as is. This description is independent on the instrument model, which implements the second step of the forward model. Application of the instrument model to the forward solution yields simulated observables.

In the inverse process of retrieval, we proceed from observables to the subset of model parameters intended to be retrieved, usually referred to as the *state vector*. Proceeding from the effect to the cause does result in specific complications, usually nonexistent in the process of forward modeling. In general, inverse problems are nonlinear and have to be solved iteratively. At each step, a corresponding linearized inverse problem is solved, which has the form of a matrix equation

$$\mathbf{K}(\mathbf{p}_{k+1} - \mathbf{p}_k) = \mathbf{R}_{obs} - \mathbf{R}_k$$

where the vector of observables $\mathbf{R}_k$ and matrix of sensitivities $\mathbf{K}$ are calculated for the current iteration of the state vector $\mathbf{p}_k$, $\mathbf{R}_{obs}$ is the vector of measured observables, and $\mathbf{p}_{k+1}$ is the next iteration of the state vector. Depending on the physics of the forward model, there are two types of inverse problem: well-posed problems and ill-posed problems.

Well-posed problems do not require any additional information about the state vector, other than that provided by the measured observables themselves. The number of independent observables has to be no less than the number of model parameters in the state vector. Additional observables – dependent or independent – will result in decrease of retrieval errors.

Ill-posed problems cannot be solved in principle without invoking some additional information about the state vector known prior to retrieval, referred to as *a priori information*. This happens, for example, when the state

vector includes continuous parameters, which are functions of relevant arguments – usually, space coordinates and/or time. Vertical profiles of atmospheric parameters provide a good example. Another example, although not from the area of geophysics, is the trajectory of a celestial object – its position in the selected system of coordinates as a function of time.

The a priori information can be of various forms. In such case as retrievals of profiles of atmospheric parameters, this information can be provided in the form of covariance matrices of these parameters – derived from statistics of previous measurements, or just guessed from some considerations. In such case as trajectory retrievals, the a priori information can be in the form of requirements on smoothness of the solution in terms of the time derivative of a suitable order.

In most practical cases, the forward models are nonlinear and so are the corresponding inverse problems. They have to be linearized and solved iteratively. At each iteration, the solution sought is the correction of the state vector providing the best fit to the residuals – differences between measured and simulated observables. The linearized inverse problem has a form of a linear algebraic matrix equation, which can be solved using existing numerical recipes.

Any physical measurement is meaningful if and only if its result is obtained along with an estimate of its uncertainty. Thus, the solution of inverse problems in geophysical retrievals needs to be complemented by its error analysis. If the forward model accurately describes the subject of retrieval and the procedure of measurement and the resulting inverse problem is well-posed, then the measurement errors are the only source of retrieval errors. Resulting retrieval errors are commonly referred to as *error bars*.

If the inverse problem is ill-posed, then invoking a priori information results in an additional kind of retrieval errors. For example, vertical profiles retrieved in atmospheric remote sensing have finite vertical resolution, i.e., there are uncertainties in benchmarking of retrieved values against the vertical coordinate in the atmosphere. Resulting retrieval errors are referred to as *smoothing errors*.

Finally, any forward model represents only an approximation of the reality, and corresponding *forward model errors* contribute to retrieval errors. If formulation of the forward model itself is accurate, then the only source of forward model errors is due to uncertainties of model parameters outside of the state vector subset. But the forward model may contain uncertainties in its formulation. As Clive Rodgers states in his monograph (Rodgers, 2000), “then modeling error can be tricky to estimate.”

Summary

A necessary premise for development of geophysical retrieval algorithms is an availability of an adequate forward model, which, for the given set of model parameters, provides accurate values of simulated observables along with sensitivities of the observables to the state vector.

Global Climate Observing System, Figure 1 Block diagram of principal components of geophysical retrieval.

Another necessary premise is an availability of the adequately formulated inverse problem, solution of which provides the retrieval – a best estimate of the state vector corresponding to measured values of observables – along with estimates of uncertainties of this retrieval due to measurement errors, specifics of the inverse problem, and quality of the forward model. An assembly of the forward model and inverse problem into a robust framework of the algorithm of geophysical retrieval is a challenge, and success in meeting this challenge is a necessary premise of the success of any remote sensing project.

Principal components of geophysical retrieval discussed in this entry are illustrated in [Figure 1](#). (For further details, see [Geophysical Retrieval, Forward Models in Remote Sensing](#) and [Geophysical Retrieval, Inverse Problems in Remote Sensing](#)).

There is a vast amount of literature describing geophysical retrieval as a whole, as well as different aspects of it, both in forward modeling and in solution of corresponding inverse problems. A short list below is notably incomplete and reflects personal preferences of the author. The reader is encouraged, once he/she gets a big picture to do independent search for this literature and to surf the Internet for this purpose.

GLOBAL CLIMATE OBSERVING SYSTEM

Jean-Louis Fellous

Committee on Space Research (COSPAR) Secretariat,
Paris, France

Definition

Albedo. The fraction of solar energy reflected from the Earth back into space.

Fraction of absorbed photosynthetically active radiation (FAPAR). The solar radiation reaching the surface on the 0.4–0.7 μm spectral region is known as the photosynthetically active radiation (PAR). FAPAR refers to the fraction of PAR that is absorbed by a vegetation canopy.

Leaf area index. The ratio of total upper leaf surface of vegetation divided by the surface area of the land on which the vegetation grows.

Permafrost. Soil at or below the freezing point of water (0°C or 32°F) for 2 or more years.

Phytoplankton. Photosynthetic or plant constituent of plankton, mainly composed of unicellular algae.

Introduction

The Global Climate Observing System (GCOS) was established in 1992. GCOS is an international mechanism aimed at coordinating observing systems and networks for meeting the needs for climate observation at national and global level. GCOS serves as the climate component of the *Global Earth Observation System of Systems (GEOSS)*. It is cosponsored by four international bodies: the World Meteorological Organization (WMO), the Intergovernmental Oceanographic Commission (IOC) of UNESCO, the United Nations Environment Programme (UNEP), and the International Council for Science (ICSU).

GCOS objectives

GCOS's main role is to ensure that the observations required to meeting national and international needs for climate data and information are well identified, gathered, and made widely available. Its ultimate goal is the establishment of a global, reliable, comprehensive, and sustained climate observing system, giving access to the physical, chemical, and biological properties as well as the atmospheric, oceanic, hydrological, terrestrial, and cryospheric processes that contribute the total Earth climate system and capable of detecting and monitoring its natural and man-induced changes.

GCOS activities provide the necessary support to the components of the World Climate Programme, including the World Climate Research Programme, to the assessment role of the Intergovernmental Panel on Climate Change (IPCC), and to the international policy development undertaken through the United Nations Framework Convention on Climate Change (UNFCCC).

GCOS builds on the existing observing systems operated in the context of the WMO World Weather Watch Global Observing System and Global Atmosphere Watch, the *Global Ocean Observing System (GOOS)* led by the IOC, and the *Global Terrestrial Observing System (GTOS)* led by the Food and Agriculture Organization (FAO) and associated Global Terrestrial Networks. It essentially relies upon observing system elements funded and operated at national level. It includes in situ, airborne, and space-based observational components.

GCOS implementation

A GCOS Steering Committee is charged with the responsibility of providing scientific and technical guidance to the sponsoring and participating organizations for the planning and implementation of the observing system. Scientific advisory panels have also been established to provide expert advice in each domain (atmosphere, ocean, and land surface). These panels are consulted on the appropriate observing strategy and the measurement requirements and contribute to assessing the status of observing networks and systems. A Secretariat located at the WMO Headquarters in Geneva, Switzerland, supports the activities of the Steering Committee, the GCOS panels and the GCOS program as a whole.

The overall plan for the global climate observing system was developed over the 1992–1995 period. GCOS, in consultation with its partners, further prepared and published in 2004 an Implementation Plan (GCOS, 2004) that addressed the requirements identified in the Second Report (GCOS, 2003) on the Adequacy of Global Observing Systems for Climate in Support of the United Nations Framework Convention on Climate Change. This plan specifically responded to the request of the Conference of the Parties to the UNFCCC. It was further complemented in 2006 with a Supplement (GCOS, 2006) specifically dedicated to space-based observations.

Essential climate variables

The GCOS Implementation Plan (GCOS-IP) is based on the needs and requirements relating to the observation of a key list of “essential climate variables” (see Table 1 below) that were identified as technically and economically feasible to observe and having critical impact with respect to the scientific requirements for systematic climate monitoring. The GCOS-IP specified 131 actions in the atmospheric, oceanic, and terrestrial domains to address the observing system needs of the UNFCCC. It outlined a comprehensive program to implement these actions by national, regional, and international entities and focused on needed improvements for observation of 44 essential climate variables (ECVs) for the atmosphere, oceans, and land.

Climate monitoring principles

Global climate change provides a specific challenge for climate monitoring, both through the need for global

Global Climate Observing System, Table 1 Essential climate variables

Domain	Essential climate variables	
Atmospheric (over land, sea, and ice)	Surface	Air temperature, precipitation, air pressure, surface radiation budget, wind speed and direction, water vapor
	Upper air	Earth radiation budget (including solar irradiance), upper-air temperature, wind speed and direction, water vapor, cloud properties
	Composition	Carbon dioxide, methane, ozone, other long-lived greenhouse gases, aerosol properties
Oceanic	Surface	Sea-surface temperature, sea-surface salinity, sea level, sea state, sea ice, current, ocean color (for biological activity), carbon dioxide partial pressure
	Subsurface	Temperature, salinity, current, nutrients, carbon, ocean tracers, <i>phytoplankton</i>
Terrestrial	River discharge, water use, ground water, lake levels, snow cover, glaciers and ice caps, permafrost and seasonally frozen ground, albedo, land cover (including vegetation type), fraction of absorbed photosynthetically active radiation, leaf area index, biomass, fire disturbance, soil moisture	

coverage and because the rate of change of climate variables (such as average temperature, sea level, and rainfall) tends to be small compared with the “background noise” of natural climate variability. Thus, particular attention to the quality and consistency of observations is needed for climate monitoring. In an attempt to help extend the compliance with the general standards and good practices for climate observation, GCOS has thus developed a set of ten “climate monitoring principles” for the collection, archival, and analysis of observations, which were endorsed by the UNFCCC in 1999. GCOS further proposed ten additional satellite monitoring principles that were agreed by the world’s space agency members of the Committee on Earth Observation Satellites (CEOS) in 2003. These principles are reproduced in Table 2 below.

The status of the global climate observing system

In December 2005, the GCOS Secretariat was invited to provide a comprehensive report in June 2009 on progress with actions recommended in the GCOS-IP to maintain, strengthen, or otherwise facilitate global observations of the climate system, including adherence to the GCOS Climate Monitoring Principles. In response to this invitation, a report was submitted to the UNFCCC in April 2009 and

Global Climate Observing System, Table 2 Climate monitoring principles

Effective monitoring systems for climate should adhere to the following principles:

1. The impact of new systems or changes to existing systems should be assessed prior to implementation
2. A suitable period of overlap for new and old observing systems is required
3. The details and history of local conditions, instruments, operating procedures, data processing algorithms, and other factors pertinent to interpreting data (i.e., metadata) should be documented and treated with the same care as the data themselves
4. The quality and homogeneity of data should be regularly assessed as a part of routine operations
5. Consideration of the needs for environmental and climate monitoring products and assessments, such as IPCC assessments, should be integrated into national, regional, and global observing priorities
6. Operation of historically uninterrupted stations and observing systems should be maintained
7. High priority for additional observations should be focused on data-poor regions, poorly observed parameters, regions sensitive to change, and key measurements with inadequate temporal resolution
8. Long-term requirements, including appropriate sampling frequencies, should be specified to network designers, operators, and instrument engineers at the outset of system design and implementation
9. The conversion of research observing systems to long-term operations in a carefully planned manner should be promoted
10. Data management systems that facilitate access, use, and interpretation of data and products should be included as essential elements of climate monitoring systems
Furthermore, operators of satellite systems for monitoring climate need to:
 - (a) Take steps to make radiance calibration, calibration monitoring, and satellite-to-satellite cross-calibration of the full operational constellation a part of the operational satellite system
 - (b) Take steps to sample the Earth system in such a way that climate-relevant (diurnal, seasonal, and long-term interannual) changes can be resolved. Thus satellite systems for climate monitoring should adhere to the following specific principles:
11. Constant sampling within the diurnal cycle (minimizing the effects of orbital decay and orbit drift) should be maintained
12. A suitable period of overlap for new and old satellite systems should be ensured for a period adequate to determine inter-satellite biases and maintain the homogeneity and consistency of time-series observations
13. Continuity of satellite measurements (i.e., elimination of gaps in the long-term record) through appropriate launch and orbital strategies should be ensured
14. Rigorous prelaunch instrument characterization and calibration, including radiance confirmation against an international radiance scale provided by a national metrology institute, should be ensured
15. Onboard calibration adequate for climate system observations should be ensured and associated instrument characteristics monitored
16. Operational production of priority climate products should be sustained and peer-reviewed new products should be introduced as appropriate
17. Data systems needed to facilitate user access to climate products, metadata and raw data, including key data for delayed-mode analysis, should be established and maintained
18. Use of functioning baseline instruments that meet the calibration and stability requirements stated above should be maintained for as long as possible, even when these exist on decommissioned satellites
19. Complementary in situ baseline observations for satellite measurements should be maintained through appropriate activities and cooperation
20. Random errors and time-dependent biases in satellite observations and derived products should be identified

was also made available for open review by the community (GCOS, 2009).

The progress assessment for all 131 actions identified in the GCOS-IP showed that good to moderate progress had been achieved for the majority of actions. Nevertheless, in 11 % of the actions, little or no progress could be reported. The report showed evidence that developed countries had improved many of their climate observation capabilities, although commitment to sustained long-term operation remained to be secured for several important observing systems. Developing countries, however, had made only limited progress in filling gaps in their in situ observing networks, with some evidence of decline in some regions. Satellite agencies had improved both mission continuity and observational capability and were increasingly meeting the needs for data reprocessing, product generation, and access. Overall, the global climate observing system had progressed significantly, but still fell short of meeting all the climate information needs of

the UNFCCC and broader user communities at regional and national levels.

As a result, a 2010 update of the “Implementation Plan for the Global Observing System for Climate in Support of the UNFCCC” (GCOS, 2010) was prepared in response to a request by Parties to the UNFCCC expressed at the 30th session of the UNFCCC Subsidiary Body for Scientific and Technological Advice (SBSTA) in June 2009 and confirmed in UNFCCC Decision 9/CP.15 (December 2009). This updated GCOS-IP includes 138 actions and takes account of the latest status of observing systems, recent progress in science and technology, the increased focus on adaptation, enhanced efforts to optimize mitigation measures, and the need for improved predictions of climate change.

The supplemental details to the satellite-based component of the 2010 updated GCOS-IP were publicly reviewed, and comments were taken into account after consultation with the broader GCOS expert community.

The so-called Satellite Supplement (GCOS, 2011) provides additional technical detail to the actions and needs identified in the 2010 updated GCOS-IP related to satellite-based observations for climate for each of the essential climate variables. In particular, it details the specific satellite data records that should be sustained in accordance with the GCOS Climate Monitoring Principles, as well as other important supplemental satellite observations that are needed on occasion or at regular intervals.

Summary

Established in 1992, GCOS is a joint undertaking of the World Meteorological Organization (WMO), the Intergovernmental Oceanographic Commission (IOC) of the United Nations Educational Scientific and Cultural Organization (UNESCO), the United Nations Environment Programme (UNEP), and the International Council for Science (ICSU). Its goal is to provide comprehensive information on the total climate system, involving a multidisciplinary range of physical, chemical, and biological properties and atmospheric, oceanic, hydrological, cryospheric, and terrestrial processes. GCOS is intended to be a long-term, user-driven operational system capable of providing the comprehensive observations required for monitoring the climate system, detecting and attributing climate change, assessing impacts of, and supporting adaptation to, climate variability and change, as well as for application to national economic development and for research to improve understanding, modeling, and prediction of the climate system.

The increasing profile of climate change has reinforced worldwide awareness of the importance of an effective global climate observing system. This system has significantly improved over the past years, but much remains to be done to meet the needs of science and society. The consequence of not meeting these requirements would be to seriously compromise the information on, and predictions of, climate variability and change.

GLOBAL EARTH OBSERVATION SYSTEM OF SYSTEMS (GEOSS)

Steffen Fritz
 International Institute for Applied Systems Analysis,
 Laxenburg, Austria

Definition

Global Earth Observation System of Systems (GEOSS) aims to involve all countries of the world to integrate ground-based (in situ), airborne, and space-based observation networks. Those Earth observation (EO) systems which participate in GEOSS retain their existing mandates but share primary observational data as well as information derived from those observations. The sharing of and access to data is enabled through common data standards. GEOSS is designed to address nine societal benefit areas, namely, ecosystems, biodiversity, health, disasters, energy, climate, weather, water, and agriculture. GEOSS seeks to connect the producers of environmental data and decision-support tools with the end users of these products, with the aim of enhancing the relevance of Earth observations to global issues. The end result is a global public infrastructure that generates comprehensive, near-real-time environmental data, information, and analyses for a wide range of users. The Group on Earth Observations (GEO www.earthobservations.org) is coordinating efforts to build GEOSS on the basis of a 10 Year Implementation Plan (GEO, 2005) running from 2005 to 2015. GEO is a voluntary partnership of governments and international organizations. GEO meets in plenary at the senior official level and periodically at the ministerial level. Decisions are taken via consensus of GEO members.

Introduction

We are currently faced with major challenges due to the powerful processes which drive global change. These processes operate at a global scale and can only be observed, understood, and predicted by a system that operates at a supranational level. These processes can have important consequences for human well-being, and the monitoring of these processes is critical in order to understand the

complex system of the Earth's terrestrial and maritime biospheres.

It is envisaged that through GEOSS, the information available to decision makers at all levels will be improved, specifically relating to human health and safety, protection of the global environment, the reduction of losses from natural disasters, and achieving sustainable development. GEOSS is founded on the principle that better international cooperation in the collection, interpretation, and sharing of EO information is an important and cost-effective mechanism for achieving this aim (Fritz et al., 2008). GEOSS will yield a broad range of societal benefits, notably:

1. Reducing loss of life and property from natural and human-induced disasters
2. Understanding environmental factors affecting human health and well-being
3. Improving the management of energy resources
4. Understanding, predicting, mitigating, and adapting to climate variability and change
5. Improving water resource management via better understanding of the water cycle
6. Improving weather information, forecasting, and warning
7. Improving management and protection of terrestrial, coastal, and marine ecosystems
8. Supporting sustainable agriculture and combating desertification
9. Understanding, monitoring, and conserving biodiversity

These correspond to the nine societal benefit areas (SBAs) referred to as disaster, health, energy, climate, water, weather, ecosystems, agriculture, and biodiversity.

Origin of GEOSS

As a result of the Earth Summit in Brazil in 1992, Agenda 21 identified the bridging of the gap between data collection and information required by decision makers as a key priority. As a result of the Summit, three different observing systems were formed, namely, the Global Climate Observing System (GCOS), the Global Ocean Observing System (GOOS), and the Global Terrestrial Observing System (GTOS). The 2002 World Summit on Sustainable Development in Johannesburg highlighted the urgent need for coordinated observations relating to the state of the Earth. It was realized that only by linking and coordinating the current observing systems could complex Earth processes (in an increasingly environmentally stressed world) be understood (GEO, 2005). The First Earth Observation Summit convened in Washington, D.C., in July 2003, adopted a Declaration establishing the ad hoc intergovernmental Group on Earth Observations (ad hoc GEO) to draft a 10 Year Implementation Plan. The Second Earth Observation Summit in Tokyo, Japan, in April 2004 adopted a Framework Document defining the scope and intent of a Global Earth Observation System of

Systems (GEOSS). The Third Earth Observation Summit, held in Brussels in February 2005, endorsed the GEOSS 10 Year Implementation Plan and established the intergovernmental Group on Earth Observations (GEO) to carry it out (Plag, 2006).

The Group on Earth Observation (GEO)

GEO is building GEOSS on the basis of a 10 Year Implementation Plan (GEO, 2005). The GEO member governments and participating organizations are supported by the GEO secretariat based in Geneva, Switzerland. The secretariat consists of a director appointed by the executive committee, several international civil servants, and 8–10 national technical and scientific experts who are seconded to the secretariat for 2 or 3 years. The secretariat is responsible for coordinating the tasks and other activities that are driving the 10 Year Implementation Plan for GEOSS. The secretariat also services the plenary and the committees and implements outreach and other support activities.

Earth observation systems

EO systems consist of instruments and models designed to measure, monitor, and predict the physical, chemical, and biological aspects of the Earth system. Buoys floating in the oceans monitor temperature and salinity; meteorological stations and balloons record air quality and rainwater trends; sonar and radar systems estimate fish and bird populations; seismic and Global Positioning System stations record movements in the Earth's crust and interior; some 60-plus high-tech environmental satellites scan the planet from space; powerful computerized models generate simulations and forecasts; and early warning systems issue alerts to vulnerable populations.

These various systems have typically operated in isolation from one another. In recent years, however, sophisticated new technologies for gathering vast quantities of near-real-time and high-resolution EO data have become operational. At the same time, improved forecasting models and decision-support tools are increasingly allowing decision makers and other users of EO to fully exploit this widening stream of information.

With investments in EO now reaching a critical mass, it has become possible to link diverse observing systems together to paint a full picture of the Earth's condition. Because the costs and logistics of expanding EO are daunting for any single nation, linking systems together through international cooperation also offers cost savings.

Implementing GEOSS

As a networked system, GEOSS is owned by all of the GEO members and participating organizations. Partners maintain full control of the components and activities that they contribute to the system of systems. Implementation is being pursued through a work plan (GEO, 2008) currently consisting of over 70 tasks. Each task supports

one of the nine SBAs or four transverse areas and is carried out by interested organizations.

GEO work plans are triennially revised and provide the agreed framework for implementing the GEOSS 10 Year Implementation Plan 2005–2015 (www.earthobservations.org/documents). These work plans consist of a set of practical tasks that are carried out by various GEO members and participating organizations. Connections will be realized between diverse observing, processing, data-assimilation, modeling, and information-dissemination systems. This will make it possible to obtain a considerably increased range of data sets, products, and services on the key aspects of the Earth system. The plans are also focusing on enhancing the role of users and reflect the inputs and engagement of the communities of practice, taking full account of the Integrated Global Observing Strategy (IGOS, www.igospartners.org/) transition into GEO.

Governments and participating organizations have advanced GEOSS by contributing a variety of “Early Achievements.” These “First 100 Steps to GEOSS” (http://www.earthobservations.org/documents/the_first_100_steps_to_geoss.pdf) were presented to the 2007 Cape Town Ministerial Summit.

Worldwide, several parallel initiatives are contributing their data to GEOSS. Inter alia, Europe is establishing Global Monitoring for Environment and Security (GMES www.gmes.info), the USA is building the Integrated Earth Observation System (IOES <http://usgeo.gov/>), and China and Brazil are collaborating through the China-Brazil Earth Resources Satellite Programme (CBERS, www.cbears.inpe.br), which is launching a new Earth observation service that will provide state-of-the-art images of the planet to end users throughout Africa free of charge.

The ultimate objective of GEOSS is to develop the use of EO by a broad range of user communities – from both developed and developing countries and ranging from decision- and policy makers to scientists, industry, international governmental, and nongovernmental organizations. Engagement of these communities to identify their needs for new or improved data is essential to enhance the adequacy of provided services and products for a wide diversity of applications.

Data standards and data dissemination

Due to the fact that EO data is obtained from a multitude of sources, an enormous effort is required among different governments and user groups to achieve true data interoperability (Durbha et al., 2008). Therefore, common standards for architecture and data sharing are essential (see *GEOSS Best Practices WIKI* <http://wiki.ieee-earth.org/> and the GEOSS Standards and Interoperability Registry www.earthobservations.org/gci_sr.shtml). Each contributor to GEOSS must subscribe to the GEO data-sharing principles, which aim to ensure the full and open exchange of data, metadata, and products. These issues are fundamental to the successful operation of GEOSS.

The architecture of an Earth observation system refers to the way in which its components are designed so that they function as a whole. Each GEOSS component must be included in the GEOSS registry and configured so that it can communicate with the other participating systems. The GEOSS Components and Services Registry provides a formal listing and description of all the Earth observation systems, data sets, models, and other services and tools that together constitute the Global Earth Observation System of Systems (www.earthobservations.org/gci_cr.shtml).

GEOSS will disseminate information and analyses directly to users. GEO is developing the GEOPortal (www.geoportal.org) as a single Internet gateway to the data produced by GEOSS. The purpose of GEOPortal is to make it easier to integrate diverse data sets, identify relevant data and portals of contributing systems, and access models and other decision-support tools. For users without good access to high-speed Internet, GEO has established GEONETCast (<http://www.earthobservations.org/geonetcast.shtml>), a system of four communications satellites that transmit data to low-cost receiving stations maintained by the users.

Activities under the SBAs

1. SBA Disasters GEOSS implementation will bring a more timely dissemination of information through better coordinated systems for monitoring, predicting, risk assessment, early warning, mitigating, and responding to hazards at local, national, regional, and global levels (GEO, 2005). Cozannet et al. (2008) describe a prototype catalogue that was developed to improve access to information about sensor networks surveying geological hazards (geohazards). Related Project: for example, GFMC (www.fire.uni-freiburg.de/)
2. SBA Human Health GEOSS will improve the flow of appropriate environmental data and health statistics to the health community, promoting a focus on prevention and contributing to continued improvements in human health worldwide (GEO, 2005). Related Project: for example, PROMOTE (<http://www.gse-promote.org/>)
3. SBA Energy Resources GEOSS outcomes in the energy area will support environmentally responsible and equitable energy management, better matching of energy supply and demand, reduction of risks to energy infrastructure, more accurate inventories of greenhouse gases and pollutants, and a better understanding of renewable energy potential (GEO, 2005). Related Project: for example, ENVISOLAR (<http://www.envisolar.com/>)
4. SBA Climate GEOSS outcomes will enhance the capacity to model, mitigate, and adapt to climate change and variability. Better understanding of the climate and its impacts on the Earth system, including its human and economic aspects, will contribute to improved climate prediction and facilitate sustainable development while avoiding dangerous perturbations

to the climate system (GEO, 2005). A global climate observation system is essential to improve our understanding of the climate system and our ability to anticipate trends (Fellous, 2008). Related Project: for example, APEC (<http://www.apcc21.net/>)

5. SBA Water GEOSS implementation will improve integrated water resource management by bringing together observations, prediction, and decision-support systems and by creating better linkages to climate and other data. In situ networks and the automation of data collection will be consolidated, and the capacity to collect and use hydrological observations will be built where it is lacking (GEO, 2005). Related Project: for example, GRDC (<http://grdc.bafg.de/servlet/is/Entry.987.Display/>)
6. SBA Weather GEOSS can help fill critical gaps in the observation of, for example, wind and humidity profiles, precipitation, and data collection over ocean areas; extend the use of dynamic sampling methods globally; improve the initialization of forecasts; and increase the capacity in developing countries to deliver essential observations and use forecast products. Access to weather data for the other SBAs will be facilitated (GEO, 2005). Related Project: for example, TIGGE (<http://tigge.ecmwf.int/>)
7. SBA Ecosystems GEOSS implementation will seek to ensure that methodologies and observations are available on a global basis to detect and predict changes in ecosystem condition and to define resource potentials and limits. Ecosystem observations will be better harmonized and shared, spatial and topical gaps will be filled, and in situ data will be better integrated with space-based observations. Continuity of observations for monitoring wild fisheries, the carbon and nitrogen cycles, canopy properties, ocean color, and temperature will be set in place (GEO, 2005). This SBA is strongly linked to supporting the monitoring of the state of forests and to provide essential information to the UNFCCC process for REDD activities as well as the monitoring of illegal logging. Related Project: for example, POSTEL (<http://postel.mediasfrance.org>)
8. SBA Agriculture GEOSS implementation will address the continuity of critical data, such as high-resolution observation data from satellites. A truly global mapping and information service, integrating spatially explicit socioeconomic data with agricultural, forest, and aquaculture data will be feasible, with applications in poverty and food monitoring, international planning, and sustainable development (GEO, 2005). Related Project: for example, GAMS (http://www.earthobservations.org/cop_ag_gams.shtml)
9. SBA Biodiversity Implementing GEOSS will unify many disparate biodiversity-observing systems and create a platform to integrate biodiversity data with other types of information. Taxonomic and spatial gaps will be filled, and the pace of information collection and dissemination will be increased (GEO, 2005). Since biodiversity data in general is not lacking, but

often uneven in its spatial, temporal, and topological coverage as well as physically dispersed and unorganized, the GEOBON project tries to overcome these shortcomings by installing a system which aims to organize the information, increase the exchange between suppliers and users, and to create a mechanism whereby data of different kinds, from many sources, can be combined (Scholes et al., 2008). Related Project: for example, GEOBON www.earthobservations.org/cop_bi_geobon.shtml

Conclusions

Without a global effort to link all current observing systems to build the Global Earth Observation System of Systems (GEOSS), modern civilization will be struggling to understand the complex chemical, biological, and physical processes of the Earth system. Therefore, GEOSS is needed more than ever to acquire comprehensive, near-real-time environmental data, information, and analysis by users as well as decision makers to respond more effectively to the plethora of environmental challenges.

Since the establishment of the Group on Earth Observations (GEO), many early achievements have been realized. These are documented in www.earthobservations.org under each of the nine GEOSS themes or societal benefit areas (SBAs). However, the active mobilization of data users and providers will remain necessary to make GEOSS a success (Fellous, 2008).

Many EO resources have been created and are available to the global community in order to support scientists, decision makers, and the general populace. To realize a successful GEOSS, the key is to provide mechanisms that enable EO data and geospatial data from those resources to be processed, shared, and coordinated. To this end, the GEOPortal (www.geoportal.org) has been developed as the Internet gateway to the data produced by GEOSS.

Global Earth Observations (EO) may be instrumental to achieve sustainable development, but to date there have been no integrated assessments of their economic, social, and environmental benefits. The project Global Earth Observation – Benefit Estimation (GeoBene www.geo-bene.eu) is developing methodologies and analytical tools to assess the societal benefits of GEOSS. First results from the GeoBene project illustrate that the overall societal benefit is by far higher than the incremental costs necessary to establish GEOSS.

GLOBAL LAND OBSERVING SYSTEM

Johannes A. Dolman
Department of Earth Sciences, VU University
Amsterdam, Amsterdam, The Netherlands

Definition

An integrated system of in situ and remote sensing observation that provides information about the state of the global land surface.

Introduction

Land has a wide variety of natural features, slopes, vegetation, and soils that affect water budgets, carbon fluxes, and the reflective properties of the surface. Land is often covered by vegetation; importantly, almost 40 % of the Earth's land surface is now under some form of management. Land use changes the characteristics of the land surface and thus can induce important local climate effects, especially through changes in albedo, roughness, soil moisture, and evapotranspiration. Precise quantification of the rate of change is important to determine whether feedback or amplification mechanisms are operating through terrestrial processes to affect the climate system.

Humans have long history of observing state of the land surface through in situ observations. This relates not only to the earliest instrumental observations of surface air temperature by Buys Ballot, but also travelers generated extended descriptions of the state of the land surface they encountered on their travels. The advance of satellite technology has made important breakthroughs in our

observing capability, as now for the first time in history we are able to observe at global level the state of the Earth's surface. In 1983, a group of around 100 scientists met to initiate the International Satellite Land Surface Climatology Project (ISLSCP). This project was set out (Seller and Hall, 1992) to (1) monitor global-scale fluctuations of the land surface caused by human interference or climatic fluctuations, (2) further develop mathematical models designed to predict or simulate climate on various time scales, and (3) permit inclusion of land surface climatological variables in diagnostic and empirical studies of climatological variations. In 1984, CEOS (Committee on Earth Observation Satellites) was established in response to a recommendation from a Panel of Experts on Remote Sensing from Space, under the aegis of the G7 Economic Summit. This group, recognizing the multidisciplinary nature of satellite Earth observation, aims to coordinate satellite missions between the various space agencies, particularly with a view to avoid the occurrence of gaps. For the land surface, there is a specific constellation (<http://wgiss.ceos.org/lcip/>) for Land Surface Imaging established. There are three ways to observe the state of the land surface through remote sensing, in the optical, thermal, and microwave frequencies.

Microwave sensors

Active microwave instruments (radars) transmit at frequencies of around 1–10 GHz and measure the backscattered signals to generate microwave images of Earth's surface at high spatial resolutions (between 1 and 100 m) and with a swath width of around 100 km. The images produced have a similar resolution to those from high-resolution optical imagers, but radars have the capability to “see” through clouds providing data on all weather, on day/night basis. This is particularly useful to assess tropical deforestation. SAR interferometry can record the phase shift between two SAR images recorded at slightly different times, thereby providing highly accurate information on the motion of surfaces. Examples of such systems are the ASAR on ESA's ENVISAT platform, PALSAR (JAXA), and RADARSAT. An important application is also the estimation of surface soil moisture at high resolution (1 km) from active radar systems (Wagner et al., 2008) and the behavior of ice (Rignot and Kanagaratnam, 2006). Passive microwave techniques receive the microwave signal emitted from the Earth's surface. This signal can be used to retrieve soil moisture (Owe et al., 2008), surface temperature (Holmes et al., 2009), vegetation water content (Shi et al., 2008), and snow characteristics (Chang et al., 1987) at relatively large scales. The Soil Moisture and Salinity Mission from ESA (SMOS) has been successfully launched in 2009, while NASA's SMAP (Soil Moisture Active and Passive) is planned for launch in 2015. The use of P-band Synthetic Aperture Radar (SAR) is currently investigated to assess its capability to observe forest biomass from space.

Optical and thermal infrared sensors

Mid-resolution optical satellite systems image the Earth's land surface in visible, near-infrared, shortwave infrared, and thermal infrared wavelengths with spatial resolutions between 10 and 100 m. Examples include the Landsat series, the first launched in 1972, with now Landsat 7 nearing its final operational time. In 2008, the US Geological Survey made the Landsat archives – which extend back to 1972 – freely available. These data are being used to measure rates and patterns of land cover change, first on a continental and pan-tropical scale, and eventually globally. Other satellites include the Japanese ADEOS satellite, the French SPOT, and the Brazilian-Chinese CBERS satellite. High-resolution imagery is provided at 1 m resolution by the IKONOS satellite, while QUICKBIRD can achieve resolutions better than 1 m. Optical sensors are increasingly used to study fundamental properties of the land surface such as fraction of photosynthetically active radiation and Leaf Area Index (LAI). These properties can be used to assess physiological changes in the land surface and as such go beyond the more classical land use classifications (e.g., Gobron and Belward, 2009). The thermal infrared sensors have mainly been used to assess hydrometeorological state variables and fluxes (e.g., Norman et al., 1995) and geological mapping (Kahle and Goetz, 1983).

Future and new developments

Europe's first ice mission, CryoSat-2 carries a precise radar altimeter to measure changes at the margins of the ice sheets that overlay Greenland and Antarctica. By measuring thickness change in ice, CryoSat-2 will provide information on the stability of the Earth's ice sheets.

Among promising new technologies in land surface remote sensing is lidar (Dubayah et al., 2010). Spaceborne lidar has the potential to retrieve many aspects of forest structure important for carbon and ecosystem studies, including canopy height, leaf distribution, and aboveground biomass stocks. The ICESAT (Ice, Cloud, and land Elevation Satellite) mission is currently in orbit, while the planned DESDynI (Deformation, Ecosystem Structure, and Dynamics of Ice) mission will combine a multi-beam lidar with polarimetric and interferometric SAR capability to measure forest structure, biomass, and their dynamics.

Integrated global land observations

Foundations for both in situ observation networks and space-based observing components for the land surface are in place, and continuity of missions and validation still need to be strengthened. Improvements in understanding of the terrestrial components of the climate system, the causes and response of this system to change, and consequences in terms of impact and adaptation are vital to society. Increasing significance is thus being placed on terrestrial data for estimating climate forcing and better understanding of climate change and variability, as well as for impact and mitigation assessment. Recognition of

this need makes integration of remote sensing-based and in situ data a priority issue in global change research.

Summary

Land has a wide variety of natural features, slopes, vegetation, and soils that affect water budgets, carbon fluxes, and the reflective properties of the surface. To be able to observe the properties of the land surface, both in situ and remote sensing tools are needed. There are three ways to observe the state of the land surface through remote sensing, in the optical, thermal, and microwave frequencies. We briefly review the most important land applications in these domains.

We conclude that foundations exist for both the in situ observation networks and space-based observing components, but that continuity of missions and validation still need to be strengthened. Improvements in understanding of the terrestrial components of the climate system, the causes and response of this system to change, and consequences in terms of impact and adaptation are vital to society.

GLOBAL PROGRAMS, OPERATIONAL SYSTEMS

Mary Kicza

National Oceanic and Atmospheric Administration
(NOAA), Washington, DC, USA

Definition

Global programs, operational systems are international coordination mechanisms that have been established to coordinate the world's operational Earth remote sensing activities.

Introduction

Understanding the global environment requires an international effort: The mission objectives of Earth observation systems overlap, remote sensing science is conducted in universities and research centers around the world, and remotely sensed data have interdisciplinary applications. A number of international coordination mechanisms have been established to manage the world's operational Earth remote sensing activities. They address issues ranging from satellite system design and deployment to data acquisition and dissemination. Some of the major mechanisms are summarized below.

Asia-Pacific satellite data exchange and utilization group (APSDEU)

The Asia-Pacific Satellite Data Exchange and Utilization Group was established to increase the amount of data exchanged among agencies in the Asia-Pacific region over existing communications links, to apprise regional agencies of changes and improvements to communications and satellite systems, and to identify means of improving existing data utilization. Participants include the Japanese Meteorological Agency, the China Meteorological Administration, the Korean Meteorological Administration, the Australia Bureau of Meteorology, the Hong Kong Observatory, the Canadian Meteorological Centre, and the United States National Oceanic and Atmospheric Administration.

Committee on Earth observation satellites (CEOS)

CEOS was established in 1984 at the request of the Economic Summit of Industrialised Nations Working Group (G7) as the international forum for Earth observing space agencies. CEOS contributes the space component of the Group on Earth Observation's Global Earth Observation System of Systems and supports key stakeholders with a wide range of Earth observation data, products, and expertise.

CEOS coordinates civil spaceborne observations of the Earth and operates through the best efforts of its 30 members (space agencies) and 22 associates via voluntary contributions. Participating agencies strive to address critical scientific questions and to plan satellite missions without unnecessary overlap. CEOS has three primary objectives in pursuing this goal: (1) to optimize benefits of

spaceborne Earth observations through cooperation of its members in mission planning and in development of compatible data products, formats, services, applications, and policies; (2) to serve as a focal point for international coordination of space-related Earth observation activities; and (3) to exchange policy and technical information to encourage complementarity and compatibility of observation and data exchange systems.

CEOS is composed of four main implementation mechanisms: the CEOS Strategic Implementation Team (SIT); a permanent CEOS Secretariat; four Working Groups; and seven CEOS Virtual Constellations for GEO.

Coordination group for meteorological satellites (CGMS)

CGMS was formed in 1972 and currently has 19 member agencies and 7 observer agencies. CGMS provides a forum for the exchange of technical information on geostationary and polar-orbiting meteorological satellite systems, as well as on research and development satellite missions. CGMS works to harmonize meteorological satellite mission parameters, such as orbits, sensors, data formats, and downlink frequencies. CGMS also encourages compatibility and mutual backup for system failures through cooperative mission planning, compatible data products and services, and the coordination of space and data-related activities, thereby complementing the work of other international satellite coordinating mechanisms.

Global climate observing system (GCOS)

The Global Climate Observing System was established in 1992 as a result of the second World Climate Conference in 1990. GCOS is cosponsored by the World Meteorological Organization, the Intergovernmental Oceanographic Commission, the United Nations Environment Programme, and the International Council for Science and provides a framework for meeting worldwide requirements for a sustained and robust global system of climate observations from atmospheric, oceanic, terrestrial, and remote sensing platforms. GCOS constitutes the climate observing component of the Group on Earth Observation's Global Earth Observation System of Systems.

While GCOS neither makes observations nor generates data products itself, it stimulates, encourages, coordinates, and otherwise facilitates the taking of the needed observations by national or international organizations. GCOS provides an operational framework for integrating the observational systems of participating countries and organizations into a comprehensive climate observing system. As such, GCOS serves as the formal observations compliance mechanism for the United Nations Framework Convention on Climate Change and depends on a network of national GCOS focal points, scientists, and a multitude of operational and research agencies to implement its requirements for observing the GCOS Essential Climate Variables (ECV).

Group on Earth observations (GEO)

GEO is coordinating international efforts to build a Global Earth Observation System of Systems (GEOSS). This emerging public infrastructure is interconnecting a diverse and growing array of instruments and systems for monitoring and forecasting changes in the global environment. This "system of systems" supports policymakers, resource managers, science researchers, and many other experts and decision makers.

GEO was launched in response to calls for action by the 2002 World Summit on Sustainable Development and by the G8 (Group of Eight) leading industrialized countries. These high-level meetings recognized that international collaboration is essential for exploiting the growing potential of Earth observations to support decision making in an increasingly complex and environmentally stressed world.

GEO is a voluntary partnership of governments and international organizations. It provides a framework within which these partners can develop new projects and coordinate their strategies and investments. As of March 2012, GEO's Members included 88 governments and the European Commission. In addition, 64 intergovernmental, international, and regional organizations with a mandate in Earth observation or related issues have been recognized as Participating Organizations.

International charter "space and major disasters"

The International Charter "Space and Major Disasters" was initiated at the UNISPACE III conference in Vienna in 1999. The founding members were the European Space Agency, the French Centre National d'Etudes Spatiales, and the Canadian Space Agency.

The Charter represents a joint effort by global space agencies to put Earth observation resources at the service of rescue authorities responding to major disasters. Recognizing that no single satellite operator can address all the challenges associated with disaster management, each member agency commits resources to support the provisions of the Charter and to help mitigate the effects of disasters on human life and property.

North America-Europe data exchange group (NAEDX)

The North America-Europe Data Exchange Group was established in 1988 to optimize, maintain, and improve the exchange of meteorological data and products between Europe and North America; to maintain and update consolidated European and North American user requirements; and to provide a forum for discussions on planned changes and problems in data dissemination, processing, and formats, as well as optimization of telecommunications and IT infrastructure. Participants include Deutscher Wetterdienst, the European Center for Medium-Range Weather Forecasts, the United Kingdom Met Office, the Meteorological Service of Canada, Météo-France, the United States National Oceanic and Atmospheric Administration, and the European Organisation for the Exploitation of Meteorological Satellites.

World meteorological organization space programme (WMOSP)

The World Meteorological Organization Space Programme coordinates environmental satellite matters and activities throughout all WMO Programmes and provides guidance on the potential of remote sensing techniques in meteorology, hydrology and related disciplines, and applications. Its work includes the optimization of international space-based Earth observing capabilities with the goal of enhancing the space-based component of WMO's World Weather Watch Global Observing System.

Summary

Understanding the global environment requires an international effort. A number of international coordination mechanisms have been established to coordinate the world's operational Earth remote sensing activities that address issues ranging from satellite system design and deployment to data acquisition and dissemination. These include the Asia-Pacific Satellite Data Exchange and Utilization Group, the Committee on Earth Observation Satellites, the Coordination Group for Meteorological Satellites, the Global Climate Observing System, the Group on Earth Observations, the International Charter "Space and Major Disasters," the North America-Europe Data Exchange Group, and the World Meteorological Organization Space Programme.

Definition

GPS/GNSS Radio Occultation. An atmospheric profiling technique whereby the amplitude and phase delay of the radio signals from the global positioning satellites are observed across the Earth's limb as the satellites rise or set with respect to the receiving platform.

Introduction

A Global Positioning System (GPS) radio occultation (RO) system consists of a GPS receiver on a low-Earth-orbit spacecraft that is capable of tracking the radio signals transmitted by one of the GPS satellites as it rises or sets through the Earth's atmosphere. For each occultation event, the recorded measurements consist of the time series of the carrier phase and the amplitude for each of the two GPS frequencies. With precise knowledge of orbits and clocks for the transmitter and receiver, these measurements can be directly inverted to derive a vertical profile of refractive index n (or refractivity $N = (n - 1) \times 10^6$) from the surface of the Earth to the ionosphere. In the neutral atmosphere, the refractive index can be used to retrieve atmospheric pressure, temperature, and tropospheric humidity profiles with additional constraints. In the ionosphere, electron density profiles can be derived from the refractive index (Figure 1).

The GPS occultation technique has several unique properties compared to other remote sensing instruments. First, it is a coherent, active limb sounding technique that is capable of yielding atmospheric profiles with very high vertical resolution (from 100 m in the lower troposphere to about 1 km up to the middle stratosphere). Second, the GPS RO measurements are "self-calibrating," meaning that they do not need to be adjusted against external "standard" references that could drift over time. This makes the GPS occultation a valuable dataset for climate benchmarking. Third, the GPS signal frequencies are in the L-band and, therefore, essentially unaffected by the presence of clouds and precipitation. This ensures that the GPS occultation measurements will not be degraded or biased in cloudy regions or under severe weather conditions.

Instrumentation, missions, and data coverage

The RO technique was first developed to probe planetary atmospheres starting in the 1960s. The availability of freely accessible radio signals from the GPS constellation made this concept very appealing for Earth remote sensing in terms of cost-effectiveness and scientific merits (Gurvich and Krasil'nikova 1987; Yunck et al., 1988).

The first GPS RO mission was the proof-of-concept GPS/Meteorology (GPS/MET) that operated in 1995–1997 (Ware et al., 1996). It was equipped with the NASA/JPL TurboRogue GPS receiver modified to acquire and track occultation signals. The success of GPS/MET led to the inclusion of the more advanced "BlackJack" GPS RO receivers on the CHAMP (CHALLENGING Minisatellite Payload) (Wickert et al., 2001) and SAC-C (Satélite de Aplicaciones Científicas-C)

(Hajj et al., 2004) satellites, which have produced GPS RO data nearly continuously from 2001 to 2008. The twin satellites of Gravity Recovery And Climate Experiment (GRACE) also carried the BlackJack receivers, and routine occultation measurements have been made since 2006. The most dramatic addition to the suite of GPS occultation sensors in space is the six-spacecraft COSMIC (Constellation Observing System for Meteorology, Ionosphere, and Climate, also known as FORMOSAT-3) constellation launched in April 2006 (Anthes et al., 2008), which more than double the existing number of occultation soundings observed each day. The COSMIC spacecraft are equipped with the IGOR (Integrated GPS Occultation Receiver), which is based on the BlackJack design. The BlackJack/IGOR can be configured to track the GPS signal in open loop instead of the traditional phase-locked loop. Open-loop tracking is necessary for tracking the rising occultation and is essential for accurately tracking the highly dynamic signals through the moist lower troposphere (Sokolovskiy et al., 2006; Ao et al., 2009).

In addition, the ESA/EUMETSAT weather satellites MetOp are equipped with the GRAS GPS occultation receivers. The first of the series, MetOp-A, was launched in October 2006 and have been producing quality occultation data soon afterward (von Engeln et al., 2009). Other new missions currently flying (e.g., TerraSAR-X, TanDEM-X, MetOp-B, OCEANSAT-2) or in planning promise continued availability of GPS RO measurements.

The missions mentioned above are primarily polar orbit satellites in low Earth orbits. Some of the satellites are equipped with both fore- and aft-viewing antennas and could perform occultation measurements in both setting and rising configurations. Approximately 250 occultations, distributed quasi-randomly around the globe, can be obtained per antenna per satellite per day.

Atmospheric retrieval

There are four basic steps in retrieving atmospheric profiles from the GPS RO measurements: (1) calculation of bending angles, (2) removal of ionospheric effects, (3) calculation of refractivity profile, and (4) derivation of the temperature, pressure, and humidity profiles.

The bending angle profile represents a ray optics description of the GPS RO measurements. Traditionally, it is calculated from the Doppler shift of the signal, which is proportional to the rate of change of the phase (Fjeldbo et al., 1971). The "Doppler" method works well under most circumstances; however, it has two shortcomings. First, it is based on geometric optics and hence could not resolve vertical structures smaller than a Fresnel diameter (approximately 1 km in the upper troposphere and lower stratosphere). In addition, the Doppler method assumes that only one ray reaches the receiver at each time. In the moist lower troposphere, atmospheric multipaths occur frequently due to the presence of strong vertical gradients in the refractive index (Sokolovskiy, 2001). To untangle the atmospheric multipaths, diffraction-based

GPS, Occultation Systems, Figure 1 Illustration of GPS RO geometry. A GPS receiver on the low Earth orbit (LEO) measures the changes in the GPS signals as the GPS satellite rises or sets. Due to the vertical variation of the refractivity, the GPS signals are bent and are characterized by the bending angle α and impact parameter a .

methods must be used to transform the received signal from the time domain to impact parameter domain using the Canonical Transform Method (Gorbunov, 2002) or to Doppler frequency domain using the Full Spectrum Inversion (Jensen et al., 2003).

The bending angles are computed for each GPS frequency. Because the GPS signals traverse the ionosphere on its way to the receiver, the bending angles contain contributions from both the ionosphere and the neutral atmosphere. Thus, it is important to remove the ionospheric effects from the bending angles. Due to the dispersive nature of the ionosphere, the first-order (inverse frequency-squared) ionospheric effects can be removed through a linear combination of the dual-frequency bending angles (Vorob'ev and Krasil'nikova, 1994).

The ionosphere-corrected bending angle profile can now be used to compute the refractivity profile directly using the Abel inversion integral (Fjeldbo et al., 1971). Due to the exponentially decreasing atmospheric density with altitude, the bending angles in the upper stratosphere or above are small and susceptible to measurement noise. To reduce the noise in the retrieved refractivity, it is often necessary to replace the bending angles at high altitudes with simple approximations. This can introduce a significant source of uncertainty in stratospheric retrievals (Kursinski et al., 1997; Ao et al., 2006).

Finally, temperature, pressure, and water vapor profiles are derived from the refractivity profile through the use of the microwave refractivity equation (Smith and Weintraub, 1953) and the hydrostatic equation. When water vapor can be neglected, the refractivity is proportional to air density; the temperature and pressure can be determined unambiguously except for the initialization of the hydrostatic equation. At low altitudes, it is not possible to solve simultaneously for these variables without additional constraint. There exist two common

approaches. The first is to assume that temperature is known and solve for pressure and water vapor pressure (e.g., Hajj et al., 2002). The second is to use a one-dimensional variational (1-D Var) technique that provides an optimal estimation of the all these variables assuming known error characteristics of the refractivity measurements and the a priori background fields (Healy and Eyre, 2000).

The accuracy and precision of the GPS RO retrievals have been well studied (Kursinski et al., 1997; Kuo et al., 2004). Generally speaking, the GPS RO refractivity and temperature retrievals are most accurate in the altitude range of 8–25 km (upper troposphere and lower stratosphere, or UTLS), with refractivity error of 0.2 % and temperature error less than 1 K. Above 25 km, the ray bending is small so that the retrieval is susceptible to instrument noise and other systematic errors. Below 8 km, the horizontal structure of the atmosphere becomes a significant error source, leading to a refractivity error of 1–3 %.

Comparisons between GPS RO retrievals with collocated radiosonde sounding, global weather analyses, as well as infrared and microwave satellite measurements have shown that the standard deviations in UTLS are about 1 % in refractivity and 1.5 K in temperature. Analysis of collocated CHAMP and SAC-C occultations found them to be consistent to 0.1 K in the mean and 1 K in standard deviation in UTLS (Hajj et al., 2004). Even better agreement can be found among collocated COSMIC occultations, which are shown to have a standard deviation of 0.2 % in refractivity in UTLS (Schreiner et al., 2007).

Applications

GPS occultation measurements have been used to improve weather forecasts and to improve our understanding of the atmosphere and climate.

Recognizing the unique values of GPS occultation, a number of weather centers around the world have been ingesting GPS bending angle and/or refractivity measurements into their operational numerical weather prediction (NWP) models. Past studies have shown that assimilation of GPS occultation data yielded positive impacts on the forecasts (e.g., Healy and Thépaut, 2006; Cucurull et al., 2008). A key advantage of assimilating GPS occultation is that the measurements can be assimilated into the NWP models without a bias correction and thus can serve as important anchor for assimilating other measurements that do require bias correction (Poli et al. 2010).

One of the most promising applications of GPS occultation is its potential for climate benchmarking (Goody et al., 1998). Detecting small long-term climate change signals requires precise measurements that do not vary as a result of changes in instrumentation over time. The self-calibrating nature of the GPS occultation measurements means that the measurements are not subject to biases between different satellites or time-dependent drifts due to orbit changes, problems that have plagued the efforts to infer long-term temperature trends from the Microwave Sounding Unit (MSU) (Schröder et al., 2003; Steiner et al., 2007).

Another scientific area where GPS occultation has proven useful is in delineating the characteristics of the tropopause, which separates the convectively mixed troposphere (where temperature decreases with height) and the convectively stable stratosphere (where temperature increases with height). The tropopause plays a crucial role in tropical dynamics and the vertical transport of trace gases; moreover, the tropopause height can be a sensitive indicator of climate change. The high vertical resolution that GPS occultation temperature profiles makes them especially suitable for studying the tropopause (Nishida et al., 2000; Randel et al., 2003; Schmidt et al., 2004; Son et al., 2011).

There has also been active research in using GPS occultation data to infer the height of the planetary boundary layer (PBL) (Sokolovskiy et al., 2006; Basha and Ratnam, 2009; Guo et al., 2011; Ao et al., 2012). The PBL height is a key parameter that describes much of the diurnal, synoptic, and climatological processes associated with the PBL in a given region, including its cloud characterization and connections between the surface and free troposphere. It is, however, poorly determined due to a lack of global observations. The fine vertical resolution of the GPS occultation profiles along with its cloud-penetrating ability could potentially be used to provide insights into the boundary layer processes.

Summary

The GPS occultation technique offers unique capabilities in the remote sensing of the Earth's atmosphere. It provides high vertical resolution, all-weather profiling data from the planetary boundary layer to the stratosphere that are valuable for a wide range of weather and climate

applications. In particular, the measurements possess qualities that make them particularly useful for monitoring long-term climate change. The future of GPS occultation looks exciting, with a proliferation of GNSS transmitters from the European Galileo, Russian GLONASS, and Chinese Compass navigation satellites. Increased spatial-temporal coverage would especially benefit studies of tropical storms and other mesoscale phenomena.

ICE SHEETS AND ICE VOLUME

Robert Thomas
Sigma Space, Gorzow Wlkp, Poland

Definition and introduction

An *ice sheet* is a large mass of ice resting on land that is continental or subcontinental in extent, with the ice thick enough to cover most of the underlying bedrock topography. Its shape is mainly determined by the dynamics of its gravity-driven outward flow. There are only two ice sheets in the modern world, in Greenland and Antarctica, but during glacial periods there were others. At the beginning of the *Cenozoic*, some 65 million years (Ma) ago, neither Greenland nor Antarctica supported an ice sheet. Then, as greenhouse gases in the atmosphere decreased, slow, irregular cooling allowed ice masses to accumulate and survive, first as mountain glaciers and then with the first continental ice sheet forming over Antarctica as early as 33 Ma ago. Further cooling led to extensive ice formation on Arctic land areas about 2.6 Ma ago, initiating the *Quaternary* series of ice ages with warmer interglacials at roughly 0.12 Ma intervals. Cycling between cold *glacial* and warmer *interglacial* periods is driven by periodic features of Earth's orbit, with ice sheets growing when sunshine shifts away from the Northern Hemisphere and melting when northern sunshine returns. These changes are amplified by feedbacks, such as greenhouse gas concentrations that rise and fall as the ice cover shrinks and grows, and greater reflection of sunshine caused by more extensive ice ([Figure 1](#)).

Human civilization developed during the most recent (*Holocene*) interglacial, extending over the past 11,000–12,000 years (ka). Holocene warming was interrupted during the Little Ice Age (about 1250–1850 AD), when the Greenland ice sheet and most Arctic glaciers reached

their maximum Holocene extent. Since then, warming has resulted in Arctic-wide glacier recession, with similar responses becoming apparent more recently in Antarctica. These trends will continue if greenhouse gas concentrations continue to increase into the future ([Table 1](#)).

During the previous interglacial, 130–120 ka ago, Arctic summers were about 5 °C warmer than now and the Greenland ice sheet was considerably smaller than at present, with probable losses also from Antarctica, resulting in global sea level some 4–6 m above present values.

An ice sheet forms by the continual accumulation of snow on its surface. Over parts of an ice sheet, summers are warm enough to melt some of this snow, with some of the melt water percolating into the snow and refreezing and some running off the ice sheet into the ocean. The difference between local precipitation and melt-water runoff is the *surface mass balance*. As successive layers of snow build up, the layers beneath are gradually compressed into solid ice, at depths up to several tens of meters. The snow input is approximately balanced by glacial outflow, so the height of the ice sheet stays roughly constant through time. The difference between the mass of ice added by snowfall and that lost by runoff and ice motion is the *total mass balance*. The ice is driven downhill by gravity, from the highest points in the interior to the coast, where it melts at lower, warmer elevations or breaks off as icebergs. In contrast to Greenland, losses by surface melting are small in Antarctica and are primarily from the northern Antarctic Peninsula and the northernmost fringes of East Antarctica. The ice sheet spreads under its own weight, partly by *internal deformation* that increases with the cube of the driving stress which is proportional to the product of ice thickness and ice-surface slope. Internal deformation predominates where the ice is frozen to its bed and is typically slow. Where the bed of the ice sheet is at the melting point, ice may move more rapidly by

Ice Sheets and Ice Volume, Figure 1 Ice sheets showing the main features of those in Greenland (left of Figure) and Antarctica (right) (Source: K. Steffen, CIRES/University of Colorado).

Ice Sheets and Ice Volume, Table 1 The present areas and volumes of the two ice sheets, with estimates of the potential sea-level rise if they were to melt completely

	Area covered (million km ²)	Ice volume (million km ³)	Potential sea-level rise(m)
Ice sheets (total)	14.0	28	64
Greenland	1.7	3	7
Antarctica	12.3	25	57

sliding over its bed or by the deformation of water-saturated basal moraine and mud. This rapidly moving ice is generally channeled along bedrock troughs, which become further deepened as they are eroded by the moving ice. *Ice streams* are “jets” of faster ice flanked by slower flowing parts of an ice sheet, becoming outlet glaciers near the coast, where many are flanked by rock (Figure 2). Thus, for example, the fast-moving Jakobshavn Isbrae starts as an ice stream about 100 km inland that flows along a deep bedrock trough but is flanked by rock before calving *icebergs* into a long fjord on the west coast of Greenland.

The Antarctic ice sheet

Antarctica is the fifth largest and most southerly continent and is generally divided into two major regions: *West Antarctica*, including the *Antarctic Peninsula*, in the Western

Hemisphere and *East Antarctica* in the Eastern Hemisphere. The *Transantarctic Mountains* separate the two, extending 3,000 km between the Atlantic and Pacific coasts. Most of Antarctica is covered by ice, with thick, grounded *inland ice* resting on a solid bed, and the floating *ice shelves* formed partly from ice flowing onto the ocean across the *grounding line* and partly from snow that falls onto them. The inland ice and the ice shelves together constitute the ice sheet, which is surrounded by ephemeral *sea ice*. Inland ice (ice shelf) ranges in thickness up to 5 km (1.5 km), with an average of about 2,400 m (600 m). Antarctica is, on average, by far the highest of the continents, with surface elevations rising to 4,000 m in central East Antarctica. The South Pole lies within the continent, which is completely surrounded by the ocean. The ice sheet was considerably larger during the Last Glacial Maximum, some 20,000 years ago, and retreated to near its present extent within the last several thousand years and perhaps is still retreating (Figure 3).

Separation of Southern Hemisphere continents from *Gondwanaland* finally left Antarctica isolated when *Drake's Passage* separated South America from the Antarctic Peninsula about 30 million years ago. This allowed uninterrupted circulation of the *Circumpolar Current* in the *Southern Ocean*. The combination of continuous oceanic and atmospheric circumpolar circulation around Antarctica led to cooling of the now isolated continent and formation of the ice sheet. Outflow from the inland ice is organized into a series of drainage basins, separated by

Ice Sheets and Ice Volume, Figure 2 Estimated “balance” ice velocities for the ice sheets in Antarctica (*left*) and Greenland (*right*). Note that the surface velocity scale is logarithmic. The *gray* areas around Antarctica are floating ice shelves. The *black* coastal areas around Greenland are ice-sheet-free mountains, which include some glaciers and ice caps. Ice discharge at these velocities exactly balances the mass added by snowfall (Allison et al., 2009, copyright Antarctic Science Ltd 2009).

Ice Sheets and Ice Volume, Figure 3 The Antarctic ice sheet and ice shelves. Some marginal seas are named, and Drake’s Passage is to the north of the Antarctic Peninsula (Bentley et al., 2007).

ice divides, much like water flow on other continents. Most drainage basins concentrate the flow into either narrow outlet glaciers, particularly through the Transantarctic Mountains, or fast-moving ice streams, which are surrounded by slow moving ice rather than rock walls. Flow speeds increase toward the coast, because of increasing total upstream snowfall and because the ice generally thins to seaward. Where there is convergence into an outlet glacier or ice stream, the speed of flow is increased even more and can reach more than a kilometer per year.

The *West Antarctica ice sheet* (WAIS) flows mostly into the *Ross Ice Shelf* in the Ross Sea, the *Filchner/Ronne Ice Shelf* in the Weddell Sea, and smaller ice shelves in the *Amundsen Sea* which lies between the Bellingshausen and Ross Seas. The two big ice shelves are each about the area of Spain. Driven by gravity, ice shelves spread out over the ocean under their own weight, supplied with ice partly from tributary glaciers and ice streams, partly from snow that falls on their surfaces, and in some cases partly from ice frozen at basal interfaces with the ocean. Basal melting is far more common than freezing and can be as high as tens of meters per year and accounts for a large fraction of total losses, with iceberg calving from seaward ice fronts responsible for the rest. Where ice shelves run aground on shoaling seabed, *ice rumpled* or *ice rises* are formed. Ice rumpled are dragged along by surrounding ice shelf to move slowly over the sea bed; ice rises are stationary and dome shaped, with their own patterns of outward ice motion.

The Greenland ice sheet

The Greenland ice sheet occupies a latitude band extending from 60 to 80 N and covers an area of 1.7 million square km. With an average thickness of 1,600 m, it has a total volume of approximately 3 million cubic km – equivalent to a sea-level rise of about 7 m. It consists of a northern dome and a southern dome, with maximum surface elevations of approximately 3,200 m and 2,850 m, respectively, linked by a long saddle with elevations around 2,500 m. Bedrock beneath much of the ice sheet is close to sea level, but the ice sheet is fringed almost completely by coastal mountains through which the ice sheet is drained by many glaciers (Figure 4).

The ice sheet in Greenland differs substantially from that in Antarctica, which is almost ten times larger in volume. Antarctica straddles the South Pole and has a dominant influence on its own climate and on the surrounding ocean, with cold conditions even during the summer and around its northern margins. Away from the coast, much of Antarctica is a cold desert, with very low precipitation rates. There is little surface melting, even near the coast, and most of the melt water soaks into underlying snow and refreezes. Because of the cold conditions, vast floating ice shelves exist around much of the continent. Ice drainage is primarily by glaciers and ice streams, some of which penetrate deep into the heart of the ice sheet, moving at maximum speeds of a few

Ice Sheets and Ice Volume, Figure 4 The Greenland ice sheet, showing key glaciers. Black denotes rock, and gray denotes ice, shaded in 500 m elevation bands with the highest contour at 3,000 m (Prepared by S. Manizade).

hundred meters per year, apart from a few exceptions. Most glaciers and ice streams flow into ice shelves, which are also fed by snow accumulation on their surfaces. The ice shelves thin toward their seaward ice fronts, partly by ice creep and partly by basal melting, with melting rates generally of a few tens of centimeter/year, but increasing to tens of meters/year near the grounding lines of some ice shelves. Thus, ice loss from the Antarctic ice sheet is primarily by melting from beneath, and iceberg calving from seaward ice fronts, of ice shelves.

By contrast, the Greenland climate is strongly affected by its proximity to other land masses and to the North Atlantic, with the Gulf Stream to the south and regions of North Atlantic deep water production to the east and west. Ice-core data from the summit of the ice sheet indicate that Greenland temperatures and accumulation rates can increase significantly over periods of a few years

to decades (Alley et al., 1993). Other major contrasts with Antarctica include widespread summer melting, higher accumulation rates, very few ice shelves, and faster, narrower glaciers. Summer melting occurs over about 50 % of the ice-sheet surface, depending on summer temperatures, with much of the resulting melt water flowing into the sea, either along channels cut into the ice surface or by draining to the bed via crevasses. Mass loss by surface melting accounts for about half the total ice loss from Greenland, with iceberg calving responsible for the rest. Most Greenland outlet glaciers are narrower, by an order of magnitude, than their Antarctic counterparts, but some reach speeds that are an order of magnitude higher. Consequently, these glaciers drain very large volumes of ice, with discharge rates strongly determined by fast-glacier dynamics, which are poorly understood.

The polar ice sheets are remote, difficult to visit, and easily regarded as being of little significance to the rest of the world. But in two ways, they have turned out to be of growing importance: They preserve a record of past climate and climate change, and they control global sea level.

Ice cores reveal a history of climate

Most of the surface of the Antarctic ice sheet, and about half of the Greenland ice sheet, is too cold for there to be much surface melting, and snow that falls on the ice sheets is slowly compressed until air that is trapped in the snow becomes isolated into small bubbles that shrink in size at increasing depths and finally dissolve in surrounding ice. Because there is little or no surface melting, annual layers of snow accumulation are unmixed with others, and they retain a signature of past climate, which can be sampled by drilling deep ice cores from cold parts of the ice sheet. The variety of climatic proxies in these cores is greater than in any other natural recorder of climate, such as tree rings or sediment layers. They include information on past ice-sheet surface temperatures and elevations, precipitation, chemistry and gas composition of the lower atmosphere, volcanic eruptions, solar variability, sea-surface productivity, desert extent, and forest fires.

Prevailing temperatures when the snow fell can be inferred from the ratios of different isotopes of oxygen and hydrogen in its water molecules. The ocean contains both normal and “heavy” water: Roughly one molecule in 500 includes at least one extra neutron in the nucleus of an oxygen or hydrogen atom. The lighter molecules evaporate more easily, and the heavier molecules condense more easily. Consequently, as water that evaporated from the ocean is carried inland over an ice sheet, the heavy molecules preferentially rain or snow out, leaving the lighter molecules to precipitate at colder temperatures. Calibration of the ratios of heavy versus light molecules in present-day snowfall against prevailing air temperatures allows interpretation of similar ratios in snow and ice recovered by the ice cores. Because of substantial

Ice Sheets and Ice Volume, Figure 5 Ice ages, represented by variations in atmospheric carbon dioxide preserved in ice cores, are “forced” by Earth’s orbital clock, which changes the patterns of received sunlight. The big increase in carbon-dioxide concentrations over the past 100 years is shown by the dark blue vertical line.

differences between temperatures of summer and winter snowfall, annual layers can be counted down to considerable depths in regions of high snowfall, such as Greenland.

In the upper parts of a core, annual layers may also be visible, related to dustiness or summer-melt intensity. But deeper layers thin because of outward spreading of the ice sheet, and eventually individual years cannot be distinguished. Dating can also be inferred from the depths of events such as nuclear bomb fallout in the upper levels and ash layers corresponding to known volcanic eruptions. At greater depths, approximate dating can be estimated from radiocarbon or other radionuclide dating or by ice-flow modeling.

In addition to information from the isotope composition of the ice, the air bubbles and dust trapped in the ice cores allow for measurement of the atmospheric concentrations of dust and trace gases, including the greenhouse gases carbon dioxide, methane, and nitrous oxide. Total atmospheric concentration within the core at different depths indicates the air pressure, and hence surface elevation, at the time of snow deposition. Analysis of the dust and its concentration provides information on its source, and hence wind patterns, and on overall global dustiness. It also gives a strong indication of human influence on the concentration of atmospheric pollutants, such as lead and DDT. Greenhouse gas concentrations clearly show growth in these gases since the beginning of the Industrial Revolution, with a progressive acceleration in this growth as a burgeoning world population demands the fruits of affluence. Greenhouse gas concentrations are now higher than at any time during the 800,000 years covered by the ice-core record (Figures 5 and 6).

The length of the time record obtained by an ice core depends on the depth reached by the core and by the local snow-accumulation rate. It varies from a few years for

Ice Sheets and Ice Volume, Figure 6 Ice cores show these dramatic increases in greenhouse gases over the past 100 years as global energy consumption has increased.

a shallow core (typically 10 m) up to 800,000 year for the 3,200 m EPICA core in East Antarctica, which provides a climate record covering eight glacial cycles. The transition from glacial to interglacial conditions about 430,000 years ago resembles the transition into the present interglacial period in terms of the magnitude of change in temperatures and greenhouse gases. The interglacial that followed lasted 28,000 years compared to the 12,000 years recorded so far in the present interglacial period. Given the similarities between this earlier warm period and today, this may imply that, without human intervention, a climate similar to the present one would extend well into the future.

Although ice cores have revealed much about the growth and collapse of past ice sheets, little was known about their present behavior until quite recently. The past two decades have seen a dramatic change in our ability to observe the ice sheets, made possible by advances in remote-sensing techniques and their application aboard aircraft and satellites.

Applications of remote sensing to ice-sheet investigations

The polar ice sheets are remote and inhospitable and, until the 1970s, observations were largely made in situ, supplemented by just a few air photographs. Consequently, little was known about their behavior apart from the very few locations where detailed measurements had been made. Snow accumulation was measured by repeated stake measurements or by interpreting snow layers in a pit or shallow drill core. Ice motion was measured by repeatedly surveying stake locations with respect to local fixed points, by sun or star observations where there were no fixed points, or by repeated mapping of local magnetic anomalies. Ice thickness was measured

using seismic techniques. Progress was slow until, in the early 1970s, scientists at the Scott Polar Research Institute in Cambridge, England, developed a low-frequency airborne radar capable of penetrating ice and receiving a reflected signal from the ice bed. This made possible major ice-thickness surveys in both Antarctica and Greenland that advanced our knowledge substantially. Later in the same decade, NASA launched *SeaSat*, a near-polar orbiting satellite with various sensors aboard designed to observe the ocean but which also turned out to be remarkably well suited to observing the polar ice sheets.

Included aboard *SeaSat* were:

- A *passive-microwave* radiometer, which images microwave emissions from the surface. Passive-microwave data have been successfully applied to the mapping of surface melting on the ice sheets and can also be used to help interpolate estimates of snow-accumulation rates between in situ measurements (Figure 7).
- A *scatterometer*, which images microwave reflections from an onboard radar and maps areas with near-surface ice layers in addition to those with surface melting.
- A *synthetic aperture radar* (SAR), which records the time delay, the phase, and the amplitude of reflections from a side-looking radar. In addition to providing high-resolution, all-weather images of glaciers and ice sheets, the information from repeated SAR images of the same area can be used to reconstruct surface topography and to map accurate estimates of ice motion at high spatial resolution. This final capability transformed our ability to study the polar ice sheets.
- A *radar altimeter* that measures the closest range from the spacecraft to the surface beneath. Designed to measure ocean topography, this instrument was the first to provide estimates of ice thickening/thinning rates over

Ice Sheets and Ice Volume, Figure 7 The graph shows the total cumulative melt area from 1979 to 2007 for the Greenland ice sheet derived from satellite passive-microwave data. The map inserts display the area of melt for 1996, 1998, and the record year 2007 (From K. Steffen, CIRES, University of Colorado).

large regions. Unfortunately, however, the large radar beam width and the possibility of radar penetration below the ice-sheet surface make accurate interpretation very difficult.

All of these sensors clearly demonstrated the enormous potential of satellite remote sensing for ice-sheet research and have been included on various other spacecraft since. Together, they have revolutionized the study of the polar ice sheets. They have also helped focus in situ measurements by identifying regions where such measurements may be most productive. Nevertheless, some measurements are best made from aircraft, particularly after the availability for civil applications of the *Geodetic Positioning System* (GPS) in the early 1990s made it possible to reconstruct very accurately an aircraft trajectory and to follow earlier aircraft routes during repeat surveys. This capability made it possible, starting in 1991, for NASA to make accurate measurements of ice-surface elevations (to within ± 10 cm), using a scanning laser altimeter along several tens of thousands of km of flight tracks over the Greenland ice sheet. Repeat surveys in 1993 and 1998 provided the first indication that the ice sheet was losing mass overall, with slow central thickening more than balanced by far more rapid thinning nearer the coast. Ice thickness was also measured along these flight lines, providing information needed to interpret

observed thickening/thinning rates, information that cannot yet be acquired from satellite-borne sensors. Unfortunately, the remoteness and sheer size of Antarctica prevented similar surveys over the Antarctic ice sheet.

Later, in 2003, NASA launched the Geoscience Laser Altimeter System (GLAS) aboard the near-polar orbiting *ICESat* to make similar measurements over both ice sheets and the rest of Earth's surface. Unfortunately, problems with the laser system resulted in reducing its use to two or three surveys per year, each lasting about a month. The laser finally ceased operating in 2009. Data from *ICESat* confirmed the overall pattern of slow thickening over parts of central Greenland and rapid thinning over many coastal regions and revealed patterns of elevation change over Antarctica. However, cloud cover and the quite large separation between adjacent *ICESat* orbits resulted in incomplete coverage of the ice sheets, particularly in coastal regions where thinning rates are highest (Figure 8).

A joint NASA/German Aerospace Center (DLR) mission, the Gravity Recovery and Climate Experiment (*GRACE*), launched in 2002 and expected to continue operating until 2015, maps Earth's gravity field by precisely measuring the time-varying distance between two small satellites chasing each other along a near-polar orbit. Temporal changes in the gravity field result from mass shifting over, and beneath, the Earth's surface, including

Ice Sheets and Ice Volume, Figure 8 Rate of change of surface elevation for Antarctica and Greenland; the color scale shows rates of elevation change ranging from thinning of 1.5 m/year (purple) to thickening of 0.5 m/year (blue) (Pritchard et al., 2009).

the changing mass, of the polar ice sheets. Results have been widely used to infer changes in ice mass or total mass balance integrated over very large areas.

Until quite recently, the ice sheets were assumed to be approximately in *steady state*, with total snow accumulation roughly in balance with total losses by melting and ice discharge. This was not based on measurements of these parameters, but rather on very low rates of observed sea-level rise (SLR) – close to only 1 mm/year – implying very small changes in ice-sheet volume. But measuring and understanding the mass balance of the Greenland and Antarctic ice sheets and of individual drainage basins within the ice sheets have long been major goals of ice-sheet science, and the satellite and aircraft measurements described above resulted in major advances toward these goals. Fortuitously, these advances came at a time when SLR rates began to increase substantially. If the polar ice sheets were to melt completely, global sea level would rise by about 64 m, so measuring and understanding their mass balance help to explain the recent increase in SLR and to predict future SLR.

Measuring the mass balance of the polar ice sheets

Techniques for measuring total mass balance of the polar ice sheets include:

- *The mass-budget approach*, comparing gains by surface and internal accumulation with losses by ice discharge, sublimation, and melt-water runoff. Snow accumulation is estimated from stake measurements,

annual layering in ice cores, or from regional atmospheric climate modeling. Ice discharge is the product of velocity and thickness, with velocities measured by ground-based survey, photogrammetry, or, increasingly, with satellite SAR operating interferometrically, and thickness generally measured by airborne radar. Melt-water runoff is inferred from regional atmospheric climate models validated with surface observations where available. Mass-budget calculations involve the comparison of two very large numbers, and small errors in either can result in large errors in estimated total mass balance.

- *Repeated altimetry surveys*, to measure height changes, from which changes in volume and mass are inferred. Rates of surface-elevation change with time (dS/dt) reveal changes in ice-sheet mass after correction for changes in depth/density profiles and vertical bedrock motion. Satellite radar altimetry has been widely used, but data interpretation is difficult because of time-variable radar penetration into the snow and, over sloping and undulating surfaces, because of the large radar footprint. These limitations are overcome by laser altimetry, but problems with NASA's ICESat resulted in a comparatively sparse data set that poorly reveals the behavior of individual glaciers and ice streams, which are better investigated using airborne laser altimetry, with the added advantage of providing an opportunity to measure ice thickness at the same time. All altimetry mass-balance estimates include substantial uncertainties associated with settling of surface snow

Ice Sheets and Ice Volume, Figure 9 Estimates of rates of surface-elevation changes from ICESat (a), and mass changes from GRACE represented as equivalent water depth changes (b) (Riva et al., 2009).

and with density assumed to convert thickness changes to mass changes.

- *Satellite measurements of temporal changes in gravity*, to infer mass changes directly. Since 2002, the GRACE satellite has measured Earth's gravity field and its temporal variability. After removing the effects of tides, atmospheric loading, spatial and temporal changes in ocean mass, etc., high-latitude data contain information on temporal changes in the mass distribution of the ice sheets and underlying rock. Mass-balance estimates are – at coarse resolution – several hundred kilometers, but this has the advantage of covering entire ice sheets, which is extremely difficult using other techniques. Consequently, GRACE estimates include mass changes on the many small ice caps and isolated glaciers that surround the big ice sheets, which are strongly affected by changes in the coastal climate. Error sources include measurement uncertainty, leakage of gravity signal from regions surrounding the ice sheets, and causes of gravity changes other than ice-sheet changes. Of these, the most serious are the gravity changes associated with vertical bedrock motion (Figure 9).

Mass balance of the Greenland and Antarctic ice sheets

Most model results previously suggested that climate warming would result primarily in increased melting from coastal regions and an overall increase in snowfall, with probably a small mass loss from Greenland and a small gain in Antarctica during the twenty-first century, and

little combined impact on sea level. But recent measurements using the techniques described in the last section show substantial losses from both ice sheets but with poor agreement between estimates from the three different techniques. Moreover, each technique is under continual development and improvement, so that estimates based on the same set of measurements are continually changing. Nevertheless, the three independent techniques for estimating mass balance do provide the means for cross-checking results, and they increase our confidence in results where there is general agreement.

Available results indicate that annual ice loss from the Greenland ice sheet during the period with good observations increased from a few tens of cu km in the mid-1990s to perhaps as much as 200 cu km for the most recent observations. Near-coastal summer melting has increased substantially, but this is largely balanced by increased snowfall further inland, and an increasing proportion of the ice loss is by enhanced ice discharge down accelerating glaciers. Over the same period, net loss from Antarctica increased from probably near zero in the mid-1990s to nearly 100 cu km/year since 2000, almost entirely because of increased ice discharge along accelerating glaciers in West Antarctica and the Antarctic Peninsula (Figures 10–12).

Dynamic response of outlet glaciers to ice-shelf breakup

Recent rapid changes in marginal regions of both ice sheets include regions of glacier thickening and slowdown

Ice Sheets and Ice Volume, Figure 10 Antarctica, showing rates of surface-elevation change derived from satellite radar-altimeter measurements. The graph on the *right* shows rates at which the ice-sheet mass was estimated to be changing based on radar-altimeter data (*black*), mass-budget calculations (*red*), and satellite gravity measurements (*blue*). Rectangles depict the time periods of observations (*horizontal*) and the upper and lower estimates of mass balance (*vertical*). Note that an ice loss of about 360 Gt/year ($=400 \text{ km}^3/\text{year}$) raises sea level by 1 mm/year (Figure compiled by R. Thomas and S. Manizade).

but mainly acceleration and thinning, with speeds of some glaciers more than doubling. Most of these accelerations closely followed reduction or loss of ice shelves. Such behavior was predicted 40 years ago by John Mercer, based on evidence left by previous ice ages, and by Terry Hughes, based on the surface profiles of existing glaciers flowing into the Ross Ice Shelf. Soon after, Bob Thomas found evidence for the buttressing effects of ice shelves in his measurements of ice-shelf spreading rates. But the suggestion was discounted by most glaciologists as recently as the Third IPCC Assessment Report on Climate Change in 2001, based largely on results from prevailing model simulations. Soon after this, however, total breakup of the floating ice tongue of Jakobshavn Glacier in Greenland, preceded by its very rapid thinning and followed by doubling of the glacier velocity to 14 km/year, clearly showed the sensitive link between floating ice shelves and the glaciers that flow into them (Figure 13).

Most ice shelves are in Antarctica, where they cover an area of about 1.5 million sq km with nearly all ice streams and outlet glaciers flowing into them. Several small ice shelves on the Antarctic Peninsula collapsed in the last three decades of the twentieth century, possibly related to local atmospheric warming of about 3°C over the second half of

the twentieth century. Most of these ice-shelf breakups were closely followed by large accelerations of tributary glaciers, confirming the predictions discussed above. Based on these observations, it appears that ice shelves become vulnerable to breakup if mean annual air temperature exceeds -5°C . It is also probable that ocean warming preconditions an ice shelf for breakup by thinning the ice shelf as basal melting increases, and the very rapid thinning of the Jakobshavn floating ice tongue coincided with inflow of very warm ocean waters into the glacier's fjord.

Outlook: the future

Model results predict increasing snowfall in a warming climate in Antarctica and Greenland, but only the latter has been verified by independent measurements. These studies also show significantly increased melt-water runoff from Greenland in a warming climate, partly compensated by the increased snowfall, and data from recent years suggest an increase in net loss from the surface mass balance. Consequently, because there is summer melting over $\sim 50\%$ of Greenland already, and a small temperature rise substantially increases the area of summer melting, the ice sheet is particularly susceptible to continued warming. Model studies indicate that

Ice Sheets and Ice Volume, Figure 11 Greenland, showing rates of surface-elevation change between the late 1990s and 2003, derived by comparing satellite and aircraft laser-altimeter surveys. The graph shows rates at which the ice-sheet mass was estimated to be changing based on satellite radar-altimeter data (black), laser-altimeter surveys (green and purple), mass-budget calculations (red), temporal changes in gravity (blue). Jakobshavn, Helheim, and Kangerdlugssuaq are fast glaciers that doubled in speed recently (Figure compiled by R. Thomas and S. Manizade).

a temperature increase over Greenland by more than 3 °C would probably result in irreversible loss of the ice sheet. Moreover, this estimate is based on imbalance between snowfall and melting, and ice loss would be accelerated by changing glacier dynamics of the type we are already observing.

Although Greenland glacier tongues and ice shelves are vulnerable to ocean warming, there are few of them, most flow in deep troughs for only short distances inland, and central parts of the ice sheet are well protected by the fringe of near-coastal mountains. Antarctic Peninsula ice shelves are also small with comparatively little ice flowing into them, so their collapse has negligible impact on global sea level. Moreover, the largest ice shelves, in the Weddell and Ross Sea Embayments, are far to the south where it is considerably colder than the -5°C viability criterion cited above. Much of the ice draining from the West Antarctic ice sheet flows into these two ice shelves, with the remainder flowing into the Amundsen Sea to the north. Here, by contrast, the ice shelves are quite small and many have been thinning over the past decade or more, with associated acceleration of tributary glaciers that flow along very deep troughs. In particular, the speed

of *Pine Island Glacier* has roughly doubled since the 1970s, as its ice shelf thinned by as much as 5 m/year. This is a very large glacier, currently discharging more than 100 km^3 ice/year into the ocean – approximately double its “balance” value. Nearby glaciers have also accelerated, and this region is probably the most vulnerable in Antarctica to climate warming particularly if, as appears likely, this is accompanied by ocean warming.

The regions likely to experience future rapid changes in ice volume are those where ice is grounded well below sea level such as the West Antarctic ice sheet and large glaciers in Greenland like Jakobshavn Isbrae that flow into the sea through a deep channel reaching far inland. The interaction of warm ocean waters with the calving fronts and floating extensions of these glaciers represents a strong potential cause of abrupt change in the big ice sheets, and future changes in ocean circulation and ocean temperatures will very probably produce changes in ice-shelf basal melting, but the magnitude of these changes cannot currently be modeled or predicted. Moreover, calving, which can originate in fractures far back from the ice front, and ice-shelf breakup are very poorly understood. Inclusion of these processes in models will certainly yield sea-level projections

Ice Sheets and Ice Volume, Figure 12 The rate of mass loss, in cm/year water equivalent thickness, determined from monthly GRACE gravity field solutions. (a) The rate averaged between February 2003 and February 2007. (b) The rate averaged between February 2003 and June 2009 (Khan et al., 2010).

Ice Sheets and Ice Volume, Figure 13 Breakup of the Larsen B ice shelf. These are images from NASA's MODIS satellite sensor. Part of the Antarctic Peninsula is on the left. The image on the left (a) shows the shelf in late summer, with dark bluish melt ponds on the surface. The image on the right (b), collected only 5 weeks later, shows a large part of the ice shelf has collapsed, with thousands of sliver icebergs at the margins and a large blue area of ice fragments (Images: National Snow and Ice Data Center, Boulder, Colorado).

for the end of the twenty-first century that substantially exceed the projections presented in 2007 as part of the Fourth IPCC Assessment of Climate Change Report (0.28–0.42 m/year rise in sea level).

ICEBERGS

Donald L. Murphy
International Ice Patrol, US Coast Guard,
New London, CT, USA

Synonyms

Glacier berg; Glacier ice; Ice island

Definition

Iceberg. A floating ice mass extending more than 5 m above the sea surface, which has calved from a glacier or ice shelf (World Meteorological Organization, 2007).

Ice shelf. A thick sheet of floating ice attached to land or a glacier (World Meteorological Organization, 2007).

Introduction

Long before *RMS Titanic* struck an iceberg and sank in the North Atlantic in April 1912, mariners were well aware of the beauty and danger icebergs present. The first documented iceberg report might have been provided as long ago as the sixth century by the legendary Irish monk, St. Brendan, who reported encountering floating crystal palaces during his North Atlantic voyage. It was *Titanic*, however, that brought a sense of urgency to tracking icebergs and distributing that information to mariners, a task that was assigned to the US Coast Guard International Ice Patrol (IIP). Despite impressive technological advances in shipboard radars, electronic navigational systems, and communications, ships still collide with ice. In November 2007, the cruise ship *MS Explorer* sank 20 h after striking ice off King George Island, near

Antarctica. Fortunately, there was no loss of life. While it is not entirely clear whether *Explorer* struck sea ice or an iceberg, it is clear that the danger ice poses to ships is unabated. This threat extends to other offshore activities, such as oil production and exploration. For example, during the 2008 iceberg season in the western North Atlantic, a large number of icebergs threatened offshore oil platforms near Newfoundland, Canada. Production stopped for several days, and an exploratory drill rig suspended operations and departed the iceberg danger area.

Aside from the clear menace of icebergs to maritime safety, other reasons to examine iceberg populations include their role in mass balance and freshwater flux. Ice discharge is an integral part of ice-sheet mass balance. For instance, giant (>18.5 km long) icebergs calved from the Antarctic ice shelves and glacier tongues accounted for approximately half of the mass lost by the Antarctic ice sheet during the last 25 years (Silva et al., 2006). In the Arctic, the 2005 calving of a 66.4 km² ice island from the Ayles Ice Shelf, on Ellesmere Island, Canada (Copeland et al., 2007), reduced the area of the remaining Ellesmere ice shelves by about 7.5 %. Further, the subsequent melting of the calved icebergs contributes to the flux of freshwater to the ocean. The meltwater from the giant icebergs calved from Antarctica was shown to be significant in the Southern Ocean's freshwater balance and exceeded precipitation minus evaporation (P – E) in the Weddell Sea (Silva et al., 2006). Large icebergs also have the potential to alter the dynamics of the marine ecosystem substantially (Arrigo et al., 2002).

The earliest data on icebergs were obtained from ships. These include the extensive dataset collected by the Australian and Russian vessels in the Indian and Atlantic sectors of the Southern Ocean (Jacka and Giles, 2007; Romanov et al., 2008), the pre-World War II part of IIP's western North Atlantic iceberg dataset (IIP, 1913–1946), as well as others. The vast extent and isolated nature of the ocean regions populated by icebergs make extensive and frequent shipboard observations impractical; thus, the wide array of satellite-borne, airborne, and surface-based remote sensing instruments is particularly attractive in undertaking iceberg studies.

Iceberg properties and sizes

An iceberg is a floating ice mass extending more than 5 m above the sea surface (World Meteorological Organization, 2007). It may originate from a glacier flowing directly to the sea, such as the tidewater glaciers of Greenland (e.g., Joughin et al., 2004), or from an ice shelf. An ice shelf is a thick sheet of floating ice attached to land or a glacier (World Meteorological Organization, 2007). It may be nourished by snow falling directly on its surface. The large icebergs that calve from Antarctic ice shelves are usually referred to as tabular icebergs, while the term “ice island” is more commonly used to describe icebergs from Arctic ice shelves.

Icebergs, Table 1 Iceberg size categories used in the western North Atlantic and the Antarctic

North Atlantic (Environment Canada, 2005)			Australian Antarctic Program (Jacka and Giles, 2007)	
Description	Height (m)	Length (m)	Category	Length (m)
Growler	<1	<5	1	25–100
Bergy bit	1 to <5	5 to <15	2	100–200
Small iceberg	5–15	15–60	3	200–400
Medium iceberg	16–45	61–120	4	400–800
Large iceberg	46–76	121–200	5	800–1,600
Very large iceberg	>75	>200	6	1,600–3,200
			7	>3,200

Depending on their source, icebergs may have slightly differing compositions. The icebergs calved from Greenland's glaciers tend to be mostly glacial ice, with a density approximately that of pure ice (917 kg/m^3). Thus, approximately one-seventh of the mass of the iceberg will be above the ocean's surface (Lewis et al., 1994). The large tabular icebergs calved from Antarctic ice shelves are covered in snow, which reduces their mean density (Weeks and Mellor, 1978).

Icebergs come in a remarkable array of shapes with sizes spanning the range from a piano to a Caribbean Island. The sail height and keel depth of icebergs can vary widely depending on the shape of the iceberg. Typical freeboard heights for the large tabular icebergs calved from the major Antarctic ice shelves are 30–40 m (Jacka and Giles, 2007), while icebergs in the North Atlantic may reach heights of 100 m or more.

Iceberg length is a dominant factor in selecting the appropriate remote sensing system. The Canadian Ice Service (CIS) and IIP use a size classification scheme (Table 1) that is tailored for the icebergs entering the busy shipping lanes in the western North Atlantic Ocean. It reflects the fact that small pieces of ice can severely damage a vessel. An iceberg exceeding just a few kilometers in length is very rare. This classification scheme is wholly inadequate for the massive icebergs found near Antarctica. Although there is no universally accepted size classification scheme for Antarctic icebergs, the one used by the Australian Antarctic Program (Table 1) accounts for a wider range of large icebergs. To further emphasize the size disparity, an Antarctic iceberg must measure at least 18.5 km along the long axis to be entered into the United States (US) National Ice Center's (NIC) iceberg database (NIC, 2008).

Using remotely sensed information to study icebergs

Both passive and active sensors have been used successfully in iceberg studies. Passive sensors, which rely on

natural illumination and emission, include visual and infrared systems and passive microwave sensors. Active sensors, which provide their own illumination, include radar systems such as radar altimeters and imaging radars. Each has advantages and disadvantages for areal coverage, spatial and temporal resolution, and the ability to provide data irrespective of weather and light conditions. The following discussion describes a few of the sensors that have provided remotely sensed data to advance the knowledge of the distribution and behavior of icebergs. It focuses on satellite-borne instruments because of their ability to cover wide areas, a significant advantage when monitoring icebergs. The discussion includes some of the inevitable trade-offs between resolution, an indicator of the iceberg length that can be detected, and areal coverage (swath) of the instrument. For some of the instruments, the polarization of the signal is also an important characteristic. This is particularly significant to the ability of synthetic aperture radars (SAR) to distinguish between icebergs and vessels.

Visual and infrared sensors

Satellite-borne visual and infrared sensors, such as the Advanced Very High Resolution Radiometer (AVHRR) on the National Oceanic and Atmospheric Administration's (NOAA) polar-orbiting satellites and the Operational Linescan System (OLS) on the Defense Meteorological Satellite Program (DMSP) satellites, are major sources of the NIC database of giant (>18.5 km in length) Antarctic icebergs (Long et al., 2002). This database has been used in numerous studies of Antarctic iceberg populations including an examination of the contribution of giant icebergs to the freshwater flux to the Southern Ocean (Silva et al., 2006). The nominal spatial resolution of the AVHRR is 1.1 km (NOAA, 1998), while the OLS fine-mode resolution is 0.55 km (NOAA, 2008). In both cases, the resolution is well suited to monitoring large icebergs in the Antarctic. The data are of relatively low cost and are available in near real time. Unfortunately, clouds and low-light conditions during the polar winter often hamper visual and infrared sensors, which may result in data gaps.

Passive microwave systems

Because they operate in the microwave range, passive microwave systems penetrate most clouds giving them a major advantage over the visible and infrared sensors. The 85 GHz channel on the special sensor microwave imager (SSM/I) on the DMSP satellite has been used to track large Antarctic icebergs (Hawkins et al., 1991). With a 16 km by 14 km footprint, this SSM/I channel is capable of detecting icebergs of several tens of km in length and larger.

The Advanced Microwave Scanning Radiometer (AMSR-E) on the Aqua satellite, launched in 2002 and functioned until 2011, was a significant improvement over SSM/I, particularly because it has much-improved spatial

resolution. The AMSR-E's 89 GHz channel had a much smaller footprint (6 km by 4 km), allowing it to detect smaller icebergs. It has been used to track 10 km icebergs in the Antarctic (Blonski and Peterson, 2006). As with the visual and infrared sensors, passive microwave sensors are adequate for tracking the large icebergs of the Antarctic but have limited use for iceberg tracking in the northern hemisphere.

Active microwave systems

Active microwave systems are becoming the dominant remote sensing instruments in the study of icebergs in both hemispheres. They include radar scatterometers and imaging radars. Many of the instruments offer finer resolution than visual, infrared, and passive microwave systems. More importantly, these systems provide their own illumination and are not weather dependent.

Radar scatterometers were designed to measure winds over the ocean from space, but because of the high radar backscatter of icebergs, they are useful for iceberg tracking as well. The spatial resolution varies according to the specific instrument but ranges from 2.225 to 8.9 km/pixel (Long et al., 2002). The data from five scatterometers were used to study the Antarctic iceberg population continuously from 1992 by Ballantyne and Long (2002). They suggest that the increase in the number of Antarctic icebergs observed in recent years is due to the improved detection and tracking technology. Stuart et al. (2008) maintain an online database of the iceberg locations derived from the scatterometer data.

The 1978 launch of the US National Aeronautics and Space Administration's (NASA) SEASAT ushered in the era of ocean-observing synthetic aperture radars (SAR). Although SEASAT provided data for only a few months, it paved the way for a progression of SAR satellites used to monitor icebergs over a wide range of sizes in both hemispheres. Since the early 1990s, imaging radars launched by the European Space Agency (ESA), the Canadian Space Agency (CSA), and others have become increasingly capable and flexible. These instruments offer numerous beam modes with various swaths and resolutions, some with the ability to detect 30 m icebergs (Power et al., 2001). The all-weather capability and wide range of iceberg sizes that can be detected make satellite-borne SARs valuable for both operations and research.

Because small icebergs pose the greatest threat to ships, the ability to detect them is particularly significant to maritime-safety operations. Such icebergs are large enough to inflict serious damage, yet small enough to elude detection in high sea states. Two challenges dominate the operational use of SARs to detect icebergs: first, the trade-off between resolution and coverage (swath) and, second, the ability to distinguish between icebergs and vessels. CSA's RADARSAT-1 is a single-polarization radar. For high incidence angles ($>35^\circ$), it detects icebergs on the order of the resolution of the particular SAR mode. For example, in one mode, which has a 150 km swath,

icebergs 30 m or larger can be detected (Power et al., 2001). In another mode, the swath increases to 300 km, but the resolution becomes 50 m. Single-polarization images do not always provide reliable ability to distinguish between ships and icebergs. The alternating polarization mode on the Advanced SAR (ASAR) on ESA's ENVISAT, launched in 2002, permits analysis of different polarization responses of ships and icebergs (Howell et al., 2004). The increased flexibility of choosing the signal polarization offered by the RADARSAT-2 improves the discrimination skills (Scheuchl et al., 2004).

Satellite-borne SAR data are providing a rich source of information for the study of iceberg populations throughout the world's oceans. In addition, because they are capable of detecting a wide range of sizes, they give a better representation of the populations. For example, the SARs on ESA's European Remote Sensing Satellites (ERS-1, ERS-2) and RADARSAT-1 were used to study the iceberg distribution in the Eurasian Arctic. Icebergs present there are much smaller than the Antarctic, with an average size of about 100 m. SAR images showed significant iceberg production from the Renown Glacier in Franz Josef Land (Alexandrov et al., 2003). SAR data in the Antarctic have provided another resource for the extensive iceberg database being maintained at the NIC (National Ice Center, 2008).

Two trends are emerging from the identification and tracking of icebergs using SAR data. First, the data sets are becoming so large that automated systems are required to conduct consistent and efficient analysis. Computer-based techniques have been developed to locate and identify Antarctic icebergs using SAR images (Silva and Bigg, 2005), and the system also retains the iceberg shape to facilitate tracking using sequential images. Second, the process of interpreting SAR images sometimes leads to ambiguities. For example, distinguishing between small icebergs and small multiyear sea ice floes can be difficult even for a skilled analyst. Small icebergs and small vessels are also difficult to distinguish.

Summary

The last few decades have witnessed remarkable improvements in the ability of satellite-borne sensors to detect, track, and measure icebergs of wide size range. The earliest capability was limited to detecting large Antarctic icebergs in favorable weather and light conditions. Now, numerous sensors, many unencumbered by weather and light conditions, are used in both hemispheres to track icebergs as small as a few tens of meters.

An enormous increase in the amount of available data, particularly from SARs, has led to the development of automated image-analysis techniques to detect icebergs. While many of these systems have proven successful, it is widely agreed that the human analyst cannot yet be removed entirely from the process. In addition, there is still much work to be done comparing remotely sensed data with surface observations.

Finally, it is likely that human activity in ice-populated waters will increase due to resource exploitation in the ice-diminishing Arctic and growing public interest in ecotourism. This will create new challenges for many of the world's operational ice centers. Today, 20 countries (World Meteorological Organization, 2006) have organizations that provide ice services. Their success at meeting future demands hinges on the effective and efficient use of remotely sensed data.

INTERNATIONAL COLLABORATION

Lisa Robock Shaffer

MC 0553 Rady School of Management, University of California, San Diego, La Jolla, CA, USA

Synonyms

Bilateral or multilateral collaboration; International cooperation

Definition

A variety of forms of participation in remote sensing missions by organizations or individuals from more than one country. This includes space-based missions whose hardware includes components from different countries, as well as science team participation by persons

from countries other than the country of the Principal Investigator. International collaboration can also take the form of multilateral organizations in which program planning, education and outreach, calibration and validation, and other aspects of program coordination take place.

Introduction

International collaboration in remote sensing can take place in any or all elements of a typical mission: mission planning, spacecraft bus, instrument payload, launch vehicle, operations, data acquisition, and data analysis. From the simple sharing of an image acquired from space to the design of an integrated mission involving multiple partners, the history of space-based Earth observations provides examples of all levels of international engagement.

Data Sharing Across Borders: The simplest form involves someone in one country using data from a mission provided by another country. It can involve the transmission of data received centrally and distributed through terrestrial means (postal mail or electronic transmission). In the early history of Earth observations, this was typical – a magnetic tape or a copy of a photograph or other image would be created and shipped to an investigator in another country, after a competitive process of selecting a scientific research team through an international call for proposals. For some missions where there is interest in the data for purposes beyond the scientific objectives of the sponsoring agency, data have been provided on varying terms from no charge to cost of reproduction to commercial prices, sometimes without restriction and sometimes with very specific constraints on how the data could be used and by whom. Data from US weather satellites is the least restricted, and missions that have commercial dimensions such as SeaWiFS and SPOT have the most complex [data access](#) policies.

Data sharing can involve direct reception of data from one country's satellite received at a ground station in another country. The earliest form of such collaboration is probably the US weather satellites in the early 1960s. President Kennedy decreed that all the data would be openly transmitted on a global basis, and the US Government provided technical information and assistance to enable meteorological agencies around the world to receive data from the Automated Picture Transmission (APT) system. Data from NOAA satellites continues to be openly transmitted without a fee to this day, with technical support available through the World Meteorological Organization, to enable all nations, regardless of their economic status, to have vital weather information. A more complex version of this kind of cooperation continues today with remote sensing satellites including the US Landsat and French SPOT satellite series, in which ground station operators acquire data directly from the satellite but on a scheduled, fee-based arrangement.

Instrument Provision: Some satellite payloads include instruments provided by foreign space agencies. These

can be selected through a competitive process where instrument providers submit proposals to the mission lead agency, such as was done for the original NASA Earth Observing Satellite platforms and NSCAT flying on ADEOS, or specific instrument contributions can be solicited from specific providers and negotiated on a bilateral basis, such as the Search and Rescue COSPAS/SARSAT packages that fly on the polar-orbiting meteorological satellites.

Joint Missions: When there is shared planning from the inception of a mission, we refer to the type of collaboration as a joint mission. The US-French Topex/Poseidon and JASON satellites are an example, as are missions undertaken by the European Space Agency and EUMETSAT, in which the member states develop the plans for both the jointly funded elements of the payload and any national contributions as part of the mission design from the start. The Tropical Rainfall Monitoring Mission, jointly developed by NASA and NASDA is another example.

Launch and Operations: Sometimes the international collaboration comes in the form of operations support, such as provision of a launch and support for operations. The Pegasus launch of an SAC mission for Argentina and the Ukraine launch vehicle provided for GRACE are examples. In both cases, the missions themselves are also international, SAC being a collaboration between NASA and CONAE (Argentina) and GRACE involving NASA and the German space agency, DLR.

Planning and Coordination: There are several international organizations that have played a critical role in stimulating international collaboration in remote sensing. These include the World Meteorological Organization (WMO), whose coordination of meteorology predates the existence of space-based observing systems and which has been essential in the expansion of international cooperation into the satellite era. The Coordination of Geostationary Meteorological Satellite (CGMS) group (which became the Coordination Group for Meteorological Satellites) was instrumental in developing payload harmonization and backup operational arrangements for the major geostationary weather satellite systems. The Committee on Earth Observation Satellites (CEOS) was established in 1984 and has provided a venue for technical working groups on such topics as sensor calibration and validation, data cataloging, and format standards, as well as regularly convening senior space agency officials to discuss long-range mission plans and coordinate educational outreach and develop advocacy strategies to secure and expand public support and funding for space-based Earth observations.

As a result of the work of these groups and others, in 2003 the first Earth Observation Summit was convened at ministerial level and established a process that has resulted in creation of the Global Earth Observing System of Systems (GEOSS) and the Group on Earth Observations (GEO), formed in 2005 to carry out the 10 year GEOSS implementation plan.

Summary

As the need to observe and understand the planet increases in importance, and as the recognition of our global interdependence grows, it is only natural that the advanced technologies used to observe the Earth from space would stimulate international collaboration in many forms. The technological and scientific challenges require the best and brightest from across the planet to address the critical challenges of climate change and sustainability.

IONOSPHERIC EFFECTS ON THE PROPAGATION OF ELECTROMAGNETIC WAVES

Attila Komjathy
 Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA, USA

Synonyms

Ionospheric wave specification or wave propagation;
 Propagation of electromagnetic waves in the ionosphere

Definition

- *Appleton-Hartree Formula*. the equation describing the medium that is electrically neutral with constant magnetic field impressed upon it.
- *Ground and Space-Based Remote Sensing Techniques*. instruments placed on the ground or onboard satellites measuring critical ionospheric parameters and integrated electron densities (i.e., total electron content or TEC).

Introduction to ionospheric propagation

The effect of the ionosphere on electromagnetic waves propagation (see “*Electromagnetic Theory and Wave Propagation*”) can only partially be described by simple dispersion. To adequately describe the complete behavior

Ionospheric Effects on the Propagation of Electromagnetic Waves, Figure 1 System of orthogonal axes x, y, z (After Davies, 1990).

of radio waves in the ionosphere, it is important to realize that the “ionosphere is a partially ionized, spherically stratified plasma with a wide spectrum of non-uniformly spaced irregularities, upon which is imposed a non-uniform magnetic field” (Hunsucker, 1991).

The complex refractive index of the ionosphere as a magnetoionic medium was derived by the number of scientists, but the name most commonly associated with the theory is Sir Edward Appleton who was first to point out that a plane-polarized wave would be split into two opposite rotating circularly polarized waves by the magnetized plasma (Hunsucker, 1991). In 1931, Hartree suggested the inclusion of the Lorentz polarization term after which event the complex refractive index was often referred to as the Appleton-Hartree formula.

The detailed derivation of the formula can be found in Davies (1966, 1990) and Komjathy (1997). First, we have to apply Maxwell’s equations to the wave, and secondly we have to impose the properties of the medium, the so-called constitutive relations. *The Appleton-Hartree magnetoionic theory* applies to a medium that is electrically neutral with no resultant space charge and an equal number of electrons and positive ions upon which a constant magnetic field (see “*Earth Magnetic Field*”) is impressed, and the effect of positive ions on the wave is

negligible. Let us consider a plane electromagnetic wave travelling in the x direction of the orthogonal coordinate system displayed in Figure 1.

Let us also consider a uniform external magnetic field that lies in the x-y plane and makes an angle θ with the -direction of propagation. The complex refractive index n is given by the Appleton-Hartree magnetoionic dispersion equation (see e.g., Langley, 1996; Davies, 1966, 1990; Hunsucker, 1991; Hall and Barclay, 1989):

$$n^2 = 1 - \frac{X}{(1 - jZ) - \left[\frac{Y_T^2}{2(1 - X - jZ)} \right] \pm \left[\frac{Y_T^4}{4(1 - X - jZ)^2} + Y_L^2 \right]^{1/2}}, \quad (1)$$

where n is the complex refractive index ($\mu - j\chi$) with μ being the real part and χ being the imaginary part. Furthermore:

$$X = \frac{\omega_N^2}{\omega^2} = \frac{f_N^2}{f^2}, \quad (2)$$

$$Y = \frac{\omega_H}{\omega} = \frac{f_H}{f}, \quad (3)$$

$$Y_L = \frac{\omega_L}{\omega}, \quad Y_T = \frac{\omega_T}{\omega}, \quad (4)$$

$$Z = \frac{\omega_c}{\omega}, \quad (5)$$

where ω (radian/s) is the angular frequency of the “exploring wave” f (Hz), and ω_c (radian/s) is the angular collision frequency between electrons and heavier particles; ω_N is the angular plasma frequency with $\omega_N^2 = \frac{Ne^2}{\epsilon_0 m}$ with electron density N ($1/\text{m}^3$), electron charge e ($1.6 \cdot 10^{-19}$ C), permittivity of free space ϵ_0 ($8.8542 \cdot 10^{-12}$ F/m), and electron mass m ($9.1095 \cdot 10^{-31}$ kg); ω_H is the angular gyrofrequency and $\omega_H = \frac{B_o |e|}{m}$ (radian/s) with the electromagnetic field strength B_o (Wb/m²); ω_L is the longitudinal angular gyrofrequency and $\omega_L = \frac{B_o |e|}{m} \cos \Theta$ (radian/s); ω_T is the transverse angular gyrofrequency and $\omega_T = \frac{B_o |e|}{m} \sin \Theta$ (radian/s).

When collisions are negligible (i.e., $Z \approx 0$),

$$n^2 \cong \mu^2 = 1 - \frac{2X(1 - X)}{2(1 - X) - Y_T^2 \pm \left[Y_T^4 + 4(1 - X)^2 Y_L^2 \right]^{1/2}}, \quad (6)$$

then according to the magnetoionic theory, a plane-polarized electromagnetic wave will be split into two characteristic waves: an ordinary wave which approximates the behavior of a wave propagating without an imposed magnetic field displayed with a sign “+” in Equation 6, and the wave with the sign “−” is called extraordinary wave.

The *Appleton-Hartree formula* assumes that the electron collision frequency ν is not dependent on the electron velocity. In the lower D and E regions of the ionosphere where the collision frequency ν is comparable with the wave frequency ω , this assumption no longer holds. To take this effect into account it is necessary to generalize the magnetoionic theory. Now, let us go back to Equation 1, and for the sake of simplicity, we set the magnetic field strength components $Y_T = Y_L = 0$, so that

$$n^2 \cong 1 - \frac{X}{1 - iZ} = 1 - \frac{X}{1 + Z^2} - \frac{iXZ}{1 + Z^2}. \quad (7)$$

In Equation 7, after considering the real part of the refractive index only, using the binomial expansion for refractive index n , and then integrating it along the line of sight of the radio signal, we get for the ionospheric delay

$$d_{ion} \cong 40.3 \cdot \frac{TEC}{f^2 + \nu^2}, \quad (8)$$

where ν is the collision frequency (Hz). Equation 8 is very similar to Equation 7 with the difference of the inclusion of the term ν^2 . The collision frequency ν becomes comparable with the microwave frequencies in the D layer where it can be as high as 10^9 (Hz) (Komjathy, 1997). Above the D layer, ν has a value about 10^4 (Hz). Using the largest D layer electron density at the high solar activity time ($1.3 \cdot 10^9 \text{ (m}^{-3}\text{)}$) (Bilitza, 1990) and assuming that the D layer ranges from 50 up to about 90 km, it turns out that by neglecting the collision frequency, in a worst case, we are introducing an error into the ionospheric delay using microwave frequencies at the 0.05 mm level. It is interesting to point out that the inclusion of the collision frequency ν actually reduces the refracting properties of the medium.

From Equation 7, we can now define the vertical incidence reflection which takes place when $n = 0$, that is,

$$1 - \left(\frac{f_N^2}{f^2} \right) = 0, \quad (9)$$

where f_N (Hz) is the plasma frequency at which a slab of neutral plasma with density N naturally oscillates after the electrons have been displaced from the ions and are allowed to move freely. f_N can also be expressed as

$$f_N^2 = \frac{Ne^2}{4\pi^2 \epsilon_0 m}, \quad (10)$$

where the individual parameters are described earlier in this section. For earth’s ionosphere with e.g., $N = 10^{12} \text{ (m}^{-3}\text{)}$, a typical value for f_N is about 8.9 MHz (Bassiri and Hajj, 1993). The condition for a wave to be reflected at vertical incidence is $f = f_N$ which is the physical principle that will make it possible to use the techniques introduced in the following sections for ionospheric studies in geodesy and remote sensing.

Ionospheric Effects on the Propagation of Electromagnetic Waves, Figure 2 Sample ionosonde data.

Ground-based techniques for ionospheric remote sensing

In section “Introduction to Ionospheric Propagation,” we introduced the concepts of the *refractive index* for the *magnetoionic medium*, *plasma frequency*, and the *electromagnetic wave* refracting at vertical incidence (see Equation 9). Based on these principles, we will now discuss a few examples for ground- and space-based techniques as primary ionospheric remote sensing tools to measure critical ionospheric parameters and integrated electron densities (i.e., total electron content or TEC).

Ionosonde

Ionosondes function by emitting high frequency radio waves, sweeping from lower frequency to the higher, to measure the time required for the signal to travel and return from the refracting ionospheric layer. The radio-frequency pulse travels more slowly (group velocity) in the ionosphere than in free space; therefore, the virtual height is recorded instead of the true height. For frequencies approaching the maximum plasma frequency in a particular layer, the virtual height tends to become infinity because the wave has to travel a finite distance at effectively zero speed. Ionograms can

provide the relationship between the radio wave frequency and virtual height of the reflecting ionospheric layer. From the ionograms, the characteristic values of virtual heights $h_p E$, $h_p F1$, and $h_p F2$ and critical (penetration) frequencies $f_o E$, $f_o F1$, and $f_o F2$ can be scaled manually or digitally. Modern ionosondes (digisondes) routinely scale ionograms. We present a sample ionogram in Figure 2 provided by MIT’s Haystack Observatory. The data was observed with the Millstone Hill Digisonde. The radio wave frequency is plotted against the virtual height of the reflecting layer. We can clearly see that the virtual height steadily increases with the frequency up to the critical (penetration) frequency. In Figure 2, the critical frequencies $f_o E$, $f_o F1$, and $f_o F2$ can be obtained by taking a frequency reading when the virtual height has a local minimum ($f_o E$, $f_o F1$) or when it tends to approach infinity ($f_o F2$). In the figure, we can identify two curves representing the ordinary and extraordinary waves. The curves with the higher critical frequencies $f_x F1$ and $f_x F2$ are the extraordinary waves. The ordinary and extraordinary waves can be derived by using Equation 6 and then using $n = 0$ as a criterion for reflection at an ionospheric layer. After solving the equation, we will get separate solutions for the ordinary and the extraordinary waves. We can also identify a curve at the bottom of the plot which can be

Ionospheric Effects on the Propagation of Electromagnetic Waves, Figure 3 Illustration for the COSMIC concept and constellation.

attributed to background interference. The so-called 2-hop reflection is due to the twice-reflected waves from the ionospheric layers with an intermediate ground reflection (Davies, 1990).

Incoherent backscatter radar

The incoherent scatter radar is the most powerful ground-based technique for the study of the earth's ionosphere and the interactions with the upper atmosphere, magnetosphere, and the interplanetary medium (see "Radars"). The technique is based on the radar principle which is the technique for detecting and studying remote targets by transmitting a radio wave in the direction of a target and observing the reflection of the wave. The target of any incoherent scatter radar is the electrons comprising the ionosphere. Since the amount of energy scattered by each electron is well known, the strength of the echo received from the ionosphere measures the number of electrons in the scattering volume and thus the electron density. The width of the spectrum is a measure of temperature of the ionosphere which can be different for ions and electrons. The shape of the spectrum is a sensitive function of the ratio of the electron and ion temperatures. Since the mixture of ions and electrons (also known as plasma) is constantly in motion in addition to the thermal motion, an overall shift of the

spectrum can be detected from which the speed of the ions and electrons can be inferred (Komjathy, 1997).

Space-based remote sensing

We seem to be in the midst of a revolution in ionospheric remote sensing driven by the abundance of ground and space-based GPS receivers, new UV remote sensing satellites, and the advent of data assimilation techniques for space weather. The success of GPS/MET inspired a number of other radio occultation missions (see "GPS, Occultation Systems") to provide ionospheric measurements over oceanic regions, including the Argentine Satellite de Aplicaciones Cientificas-C (SAC-C), the US-funded Ionospheric Occultation Experiment (IOX), and Germany's Challenging Minisatellite Payload (CHAMP) (Jakowski et al., 2007). The joint US/Taiwan Constellation Observing System for Meteorology, Ionosphere, and Climate (COSMIC; <http://cosmicio.cosmic.ucar.edu/cdaac/index.html>), a new constellation of six satellites (see "Observational Systems, Satellite"), nominally provides up to 3,000 ionospheric occultations per day (Figure 3). The COSMIC 6-satellite constellation was launched in April 2006. COSMIC now provides an unprecedented global coverage of GPS occultation measurements (between 1,400 and 2,300 good soundings per day as of March 2009, see "Limb Sounding,

Atmospheric”), each of which yields electron density information with ~ 1 km vertical resolution. Calibrated measurements of ionospheric delay (total electron content) suitable for input into assimilation models are currently made available in near real time (NRT) from the COSMIC with a latency of 30–120 min. Similarly, NRT TEC data are available from two worldwide NRT networks of ground GPS receivers (~ 75 5 min sites and ~ 125 hourly sites, operated by JPL and others). The combined ground and space-based GPS datasets provide a new opportunity to more accurately specify the three-dimensional ionospheric density with a time lag of only 15–120 min. With the addition of the vertically resolved occultation data, the retrieved profile shapes are expected to model the hour-to-hour ionospheric “weather” much more accurately. JPL has begun integrating COSMIC-derived TEC measurements with ground-based GPS TEC data and assimilating these data into models such as JPL/USC Global Assimilative Ionospheric Model (GAIM) (originally sponsored by the US Department of Defense) so that three-dimensional global electron density structures and ionospheric drivers can be estimated.

The arrival of global, continuous datasets from diverse sources such as over 1,200 GPS receivers across the globe, satellite–satellite crosslink occultations, digisonde profiles, in situ satellite density measurements, and ultraviolet (UV) airglow measurements from low-Earth orbiters fueled the need to create models which are entirely data driven such as the persistence-driven thin shell model GIM (e.g., Mannucci et al., 1998; Komjathy et al., 2005) and various tomographic models such as MIDAS (Dear and Mitchell, 2006), EDAM (Angling and Cannon, 2004), and others (e.g., Rius et al., 1997). Further approaches, such as IDA3D (Bust and Crowley, 2007; Bust and Mitchell, 2008), attempt to incorporate data and ionospheric physics by use of models to define the a priori state of the ionosphere. In spite of high success in regions with excellent data coverage, these techniques are limited in forecasting ability. Newly emerged assimilative models involve first-principle physical models and yet also take in data, like the tomographic models, in an attempt to merge the benefits of both techniques. JPL/USC GAIM (e.g., Pi et al., 2003, 2004; Hajj et al., 2004; Wang et al., 2004; Mandrake et al., 2005), USU GAIM (e.g., Schunk, 2002; Scherliess et al., 2006), and the Fusion Numeric’s assimilation model (e.g., Khattatov et al., 2004; Angling and Khattatov, 2006) have all been developed to address this need with significant variations in the forward modeling and data assimilation approaches to better characterize ionospheric specifications.

Conclusion

The advent of real-time global ground- and space-based measurements is expected to revolutionize the accuracy of ionospheric propagation specification, nowcast, and forecast. Recently, the NOAA Space Weather Prediction Center developed a new data assimilation product

(Fuller-Rowell, 2005) that characterizes ionospheric TEC over the United States. In the next years, the real-time characterization of the global ionosphere is expected to become a standard product. This characterization will rely heavily on data from GPS measurements, but it will be enhanced by the real-time measurements from other sensors such as ionosondes or incoherent backscatter radars. As technology advances, societies of tomorrow are expected only to increase their need for highly accurate communications and navigation systems. Through collecting new data and finding new ways of analyzing ground and space-based GPS data to minimize signal propagation errors, scientists and operators will be sure to meet these future needs.

Definition

Irrigation management. The decision process and action of applying a chosen depth of irrigation water using a chosen application method at a chosen time to achieve defined agronomic and economic objectives.

Supervisory control and data acquisition (SCADA) system. An electronic hardware and software system that acquires data from sensors and controls the operations of other hardware in a supervisory fashion.

Irrigation automation. The use of in situ, remotely sensed, or near-surface remotely sensed crop, soil, and micrometeorological properties sensed by a supervisory control and data acquisition system as inputs to a decision-making algorithm in the system, which then applies defined amounts of water at defined times automatically through control of an integrated irrigation application system.

Introduction

Irrigation has been practiced around the world for thousands of years. Irrigation works greater than 6,000 years old have been found in regions as diverse as Southeast Asia, the Indian subcontinent, Central Asia, the Middle East, Egypt, and North and South America. Some of these systems simply diverted water during floods and allowed it to spread on otherwise unflooded valley lands. Others were more sophisticated and allowed diversion of water from permanent stream flow so that irrigation could occur more or less on demand. Although irrigation management occurs anytime that irrigation occurs, only in the latter systems did management include the aspects of application timing and amount. Early irrigation management involved two methods of sensing irrigation needs, either probing of the soil or observation of plant characteristics such as wilting or folding leaves and leaf color. Unfortunately, changes in plant characteristics observable by the human eye tend to occur only after there has been some loss of potential yield. As irrigation methods grew more sophisticated, so did the means of deciding when and how much water to apply. Tubular probes for extracting deep soil

USDA is an equal opportunity provider and employer.

Robert G. Evans has retired.

cores allow the soil water content below the surface to be examined, and the “feel and appearance” method of judging soil water content was regularized through studies that established the relationships between the feel and appearance of a handful of soil and its particle size distribution and water potential energy. Practical instrumentation for soil water sensing for irrigation management became widespread after the introduction of the neutron moisture meter (NMM) in the 1950s, but it was not until the 1980s that automated soil water sensors based on electromagnetic (EM) physics became available and not until the 1990s that they became widely available. In the meantime, irrigation management based on electronic sensing of plant condition remained largely in the realm of scientific studies.

After the publication of Penman’s (1948) seminal paper, which established a theoretical basis for estimating plant water use (transpiration) from measurements of wind speed, solar radiation, air temperature, and humidity, a third and less direct paradigm for irrigation management was born. The new concept was based on the observation that crop water use varied with crop development (increasing with leaf area expansion) and with the evaporative demand, which could be estimated using Penman’s equation. Later, Jensen (1968) defined a crop coefficient, K_c , as the ratio of actual crop water use ET_c to a potential or reference water use, ET_o :

$$K_c = ET_c / ET_o \quad (1)$$

The variation of K_c with crop growth (and leaf area index) was empirically determined as a function of days after planting or, more recently, growing degree days (GDD), the latter providing somewhat more stable relationships for K_c (GDD). Knowing the function K_c (GDD) for a crop and region and possessing local weather data, local crop water use, ET , can be estimated as:

$$ET = K_c ET_o \quad (2)$$

This paradigm has become the dominant one in state and federal efforts to provide irrigation scheduling information to farmers in the USA as evidenced by networks of weather stations and corresponding water use prediction systems established by both federal agencies (e.g., the AgriMET program sponsored by the Bureau of Reclamation in the Pacific Northwest) and states (e.g., CIMIS in California, AZMET in Arizona, the TXHPET Network in Texas, and the Oklahoma MESONET). The best of these provide decision support to some degree. For example, for each major crop in the region, the TXHPET Network provides crop water use values for the last day, 3 and 7 days for the closest weather station, and usually for each of three or four planting dates that span the earliest and latest planting in the current season. For crops such as corn that have short-season and long-season varieties, separate sets of values are provided for each. This reduces the management time needed to make irrigation decisions to a simple calculation of water

already applied plus precipitation versus the crop water use. However, adoption by producers faces several obstacles, including lack of site specificity of weather stations, a need for corresponding in-field precipitation measurements, and an inability to characterize in-field variations in crop water use and water need. This is despite numerous and long-term efforts to improve the estimation of ET_o and K_c (GDD) by improving the theoretical underpinnings, taking into account plant cover effects and evaporation from soil more explicitly, and by improving siting and operation of weather stations (e.g., Monteith, 1965; Jensen et al., 1990; Allen et al., 1998; ASCE, 2005).

Given the current state of practice in irrigation management, the challenge for remote sensing is to provide irrigation management tools that allow producers to obtain comparable yield, yield quality, and water and nutrient use efficiencies profitably and sustainably, which means that such tools must be practical and cost-effective.

Spatial and temporal variability

Although traditional soil water, plant-based, and weather-based methods of irrigation scheduling address temporal variability of crop water need reasonably to very well, spatial variability is poorly addressed by these methods. Aerial and satellite imagery allow determination of spatial variability but often with temporal and spatial resolutions that are inadequate for day-to-day irrigation management (Jackson, 1984; Moran, 1994; Moran et al., 1997). The conjunctive use of coarse resolution thermal images with high-resolution images in the near-infrared and visible spectrums may provide solutions to the spatial resolution problem, but this is the subject of ongoing research (Kustas et al., 2004). These efforts are combined with those to merge data from satellites that return daily images with data useful for irrigation scheduling that are obtained only weekly or biweekly (Anderson et al., 2007). Such data fusion efforts were reviewed by Ha et al. (2013a, b). A key problem is that thermal infrared radiance data are the most useful for estimating crop ET , but these data are not available at high-enough temporal or spatial resolution and may even be lacking in new satellite platforms currently under development. The challenges that the status quo presents are being met by an array of near-surface remote sensing efforts, many of them using sensors that are mounted on moving irrigation systems (Evans and Sadler, 2008; Sadler et al., 2007) or on masts set in fields and some using aircraft platforms, including unmanned aerial vehicles (UAVs).

Remote sensing for irrigation management

Satellite and aerial remote sensing have become widespread only since the 1970s, although early efforts go back to the aerial photography from balloon platforms in the 1800s. As discussed elsewhere in this volume, the development of infrared film and electronic imaging in the visible spectrum and the invisible infrared and ultraviolet

spectrums allowed a new science of remote sensing of plant and soil condition to develop.

There are several approaches to irrigation management using remote sensing, including:

1. Scheduling irrigation to replace ET estimated from a reference ET (ET_o), calculated from local weather data, which is multiplied by a crop coefficient estimated with a crop coefficient function, $K_c(NDVI)$, where NDVI is the normalized difference vegetative index (NDVI) or a similar index adjusted for reflectance from soil. The NDVI is based on canopy irradiance in the red and near-infrared bands, which can be remotely sensed.
2. Scheduling irrigations at a fixed amount of water whenever a trigger to irrigate is generated by the crop water stress index (CWSI), which is estimated using remotely sensed T_s and local weather data.
3. Scheduling irrigations at a fixed amount when triggered by the time-temperature threshold index (TTTI) reaching a crop and region-specific value. The TTTI is calculated using T_s .
4. Scheduling irrigation to replace ET estimated with the field surface energy balance (FSEB), which uses remotely sensed surface temperature, T_s , determined from thermal infrared data, and data on canopy cover and surface emissivity inferred from the near-infrared (NIR) and visible bands.
5. Sensing of crop characteristics in order to guide timing, placement, and amount of fertilizer and water through irrigation (or fertigation) systems of various orders of precision. The characteristics, including crop cover fraction, nitrogen status of leaves, disease, and pest damage, all of which vary spatially and temporally, are inferred from various remotely sensed vegetative indices (VIs).

Of the five approaches listed, only the CWSI and the TTTI have been commercialized and used by irrigators, the latter recently under the name BIOTIC (The mention of trade names of commercial products in this entry is solely for the purpose of providing specific information and does not imply recommendation or endorsement by the US Department of Agriculture.) (Upchurch et al., 1996) and the former since the 1980s. Practical use of both is quite limited currently. All of these approaches are the subjects of ongoing research efforts.

The ability to create broadband (thermal infrared to ultraviolet) images and to filter them into sub-band images led to breakthroughs in plant condition and cover sensing. Multispectral vegetation indices (VIs), such as the NDVI, are derived as ratios of signal strength in particular bands. Multispectral VIs have been widely researched as means to quantify various biophysical aspects of vegetation canopies, such as leaf area index (Moran et al., 1995), crop yield (Plant et al., 2000), and percent crop cover (Heilman et al., 1982). Thus, remote sensing of VIs provides a way to synoptically and instantaneously view crop conditions.

An approach that may improve the spatial representation of crop ET_c estimation is to incorporate remote sensing observations into irrigation scheduling protocols. A promising technique, introduced in the 1980s (Bausch and Neale, 1987), utilizes multispectral VIs to estimate corn crop coefficients. More recent research has shown that observations of multispectral VIs can provide real-time surrogates of crop coefficients for a variety of crops (Bausch, 1995; Neale et al., 2003; Hunsaker et al., 2005). Moreover, the use of remote sensing to infer the spatial distribution of K_c across the landscape can improve the ability of standard weather-based ET methods to more accurately estimate the spatial crop water use within an irrigated-field (Hunsaker et al., 2007) or at the farm-scale level (Johnson and Scholasch, 2005). The VI-based crop coefficient approach has strong practical appeal due to the longstanding familiarity and widespread use of crop coefficient methods and their relative operational simplicity. Also, this approach avoids some of the pitfalls with thermal bands, namely, the coarser spatial resolution and possible exclusion from future satellites. Nevertheless, implementation of the approach could be hindered by its reliance on empirical relationships between VIs and crop coefficients, by problems associated with the transferability of crop coefficient calibrations from one region to the next, and by timeliness and cost-effectiveness of the necessary imagery (Gowda et al., 2008).

Many methods of sensing plant water stress have been developed and studied, but only a few have impacted irrigation management. Dendrometers and leaf thickness and fruit size sensors have been used, mostly for high-value fruit and nut crops, but these approaches do not lend themselves to remote sensing. One of the earliest plant-based efforts that used near-surface remote sensing and that impacted irrigation management was the crop water stress index (CWSI) developed at the US Water Conservation Laboratory in the 1970s and 1980s (Idso et al., 1977, 1981; Jackson et al., 1981). The CWSI uses crop canopy temperature, typically sensed by an infrared thermometer, along with measured air temperature, humidity, wind speed, and solar radiation. The canopy-air temperature difference ($T_c - T_a$) is normalized to lower and upper limits of canopy-air temperature differences, which represent non-water-stressed and completely water-stressed crops, respectively. The CWSI is defined as

$$CWSI = \frac{(T_c - T_a)_m - (T_c - T_a)_l}{(T_c - T_a)_u - (T_c - T_a)_l} \quad (3)$$

where the subscript “m” denotes measured, “l” denotes a lower baseline (non-water-stressed crop), and “u” denotes an upper limit (completely water-stressed crop). The $(T_c - T_a)_l$ and $(T_c - T_a)_u$ limits may be estimated on an empirical (Idso et al., 1981) or theoretical (Jackson et al., 1981) basis. Both approaches require, at minimum, measurements of air temperature and humidity. The latter approach also requires wind speed, solar radiation, and

estimates of bulk canopy resistances. Meteorological parameters were not widely available until automated agricultural weather stations began to appear during the early 1980s (Howell et al., 1984). Furthermore, it was not until this time that basic data on bulk canopy resistances became established for a wide variety of crops and local conditions. Hence, the empirical CWSI received greater attention than its theoretical counterpart early on.

As initially developed in research and deployed for irrigation management, the CWSI employed a handheld infrared thermometer used to measure canopy temperatures at one time of day near solar noon. Although theoretically enticing, the CWSI has not been widely used for irrigation management due to various problems, including lack of a stable signal during cloudy periods, difficulty in determining the lower baseline and upper limit and nonuniqueness of these limits, and problems with measuring a meaningful canopy temperature that is representative of the field crop when soil background is visible, which might occur during part or all of the irrigation season. Moran et al. (1994) extended the CWSI concept where the upper and lower limits were defined as mixtures of soil and vegetation temperatures and termed this the water deficit index (WDI). However, both the CWSI and WDI may be sensitive to small errors in the upper and lower temperature limits, which often results in values outside the theoretical range from zero to one. The effect of sunlit vs. shaded soil and a well-watered crop underlain by dry soil (e.g., subsurface drip irrigated soil, Colaizzi et al., 2003) may further confound errors in estimating these limits.

Although the early work with the CWSI was done using handheld infrared thermometers to sense the thermal infrared radiation from crop canopies, later work has shown that maps of the CWSI or WDI can be created from aerial and satellite images or images compiled from ground-based sensors aboard self-propelled irrigation systems (Colaizzi et al., 2003; Peters and Evett, 2008; O'Shaughnessy et al., 2008). For example, an empirical CWSI (eCWSI) was determined to be a robust stress index for irrigated vineyards:

$$\text{eCWSI} = \frac{T_c - T_w}{T_{\text{dry}} - T_w} \quad (4)$$

where T_c was the temperature ($^{\circ}\text{C}$) of the center of the crop canopy computed from aerial thermal images, T_w was the temperature from an artificial wet surface that acted as a substitute for the well-watered baseline temperature, and T_{dry} was estimated by adding 5°C to the maximum dry bulb temperature recorded for the specific field day (Jones, 1992; Möller et al., 2007). Similar relationships were shown for cotton grown in the Texas High Plains where calculated eCWSI values were compared to stem leaf water potential (Ψ_L) and in the South of Israel where comparisons were made with Ψ_L and stomatal conductance (Evett and Alchanatis, 2007). These empirical relationships were more robust than the theoretical model of

Jackson et al. (1981) relating crop canopy temperatures to crop water status, and they provided a basis for spatial mapping of Ψ_L at the field scale. In areas where irrigation decisions are based on Ψ_L , this modeling may replace the labor-intensive efforts of Ψ_L measurements.

Although fundamentally related to plant water status, the CWSI faces a number of problems that have so far prevented its widespread use. The well-watered baseline is a function of plant species and for a single species can vary by important amounts between varieties (e.g., cotton: Hatfield et al., 1987). Empirical determinations of lower baseline vary depending on how "well-watered" is defined. For partial canopies, emittance from soil can bias the measure of T_c , a problem for all methods that use T_c . Also, viewing angle of the infrared sensor will affect the temperature reading, as will flowering and seed filling in some crops (corn, sorghum, and wheat). Taking readings at an angle from nadir and taking readings from opposing viewpoints are techniques used to reduce these biases. However, these techniques are not easily achieved from satellite and aircraft platforms. For these reasons, the CWSI in its many forms has not been widely adopted for use in irrigation management.

The TTTI is the number of minutes in a day that a canopy is above a species-specific threshold canopy temperature. If the TTTI exceeds a threshold time (min), which is specific to a species and climatic region, then an irrigation is triggered. The threshold time was determined by finding the average number of minutes in a day throughout the irrigation season that the canopy of a well-watered crop was above the threshold temperature. The threshold temperature was originally conceived as the temperature at which photosynthetic assimilation peaks (Burke and Oliver, 1993). However, Evett et al. (1996, 2000, 2006a) showed that the threshold temperature could be varied as long as a corresponding threshold time was determined from canopy temperatures measured on a well-watered crop. The method suffers from the same viewing angle problems that affect the CWSI. And the threshold temperature may be variety specific, not just species specific. Also, the method requires a continuous record of canopy temperature throughout the daylight hours, something not readily achieved using airborne or satellite platforms. The latter problem was overcome by Peters and Evett (2004) who devised an algorithm to scale a one-time-of-day canopy temperature measurement so as to estimate a continuous course of canopy temperatures for daytime, except for 1 h after sunrise and 1 h before sunset, with sufficient accuracy to trigger irrigations using the TTTI ($<1^{\circ}\text{C}$ error). This algorithm may have utility in scaling thermal image data from airborne or satellite platforms to produce maps of TTTI values and thus maps of crop water stress over large areas.

Thermal radiometric measurements of crop canopy temperature for automatic irrigation scheduling using the TTTI have been successful for drip-irrigated plots (Evett et al., 1996) and low-energy precision application (LEPA) irrigation using a center pivot sprinkler (Peters and

Evett, 2008). This simplified approach avoids the complexity of the CWSI by relying on the feedback effect of irrigation, which by providing water to plants allows increased transpiration and resultant cooling of the canopy. Wired thermal radiometers are now being replaced with wireless infrared thermometers and wireless sensor networks to establish remote links for data collection, communication, and control of irrigation systems (O'Shaughnessy and Evett, 2007). The specific implementation of the TTTI embodied in the BIOTIC patent has been licensed and commercialized since 2008. Although it is difficult to envision application of the TTTI using data from satellite or aircraft platforms, it is readily applied using near-surface remote sensing with sensors mounted on towers or moving irrigation system superstructures. In fact, use of moving irrigation systems as sensing platforms has allowed the implementation of field mapping of crop water stress levels and relative yield potential (Peters and Evett, 2007) as well as irrigation control.

The field surface energy balance (FSEB) has long been recognized for its promise in calculating the latent heat flux, LE , due to ET , from the other energy balance terms in

$$0 = LE + G + H + R_n \quad (5)$$

where G is soil heat flux, H is sensible heat flux, and R_n is net radiation (all fluxes taken positive toward the surface, often in $W\ m^{-2}$). In field research, many or all of these fluxes are measured, but from a remote sensing perspective, the surface brightness in the thermal infrared (used to estimate T_s) and the brightness in the near-infrared and visible bands are used to estimate R_n and H . The value of G is taken as a fraction of R_n or some function of R_n and plant cover (estimated from a VI), and ET as a depth of water per unit time ($m\ s^{-1}$, positive toward the atmosphere) is evaluated as the residual

$$ET = -LE/(\lambda\rho_w) = (R_n + G + H)/(\lambda\rho_w) \quad (6)$$

where $H = \rho_a c_p (T_s - T_a)/r_a$; T_s is assumed equal to the aerodynamic surface temperature, T_o ($^{\circ}C$); r_a is aerodynamic resistance, which is calculated as a function of crop height, h_c , and wind speed, u_z ($m\ s^{-1}$), measured at an elevation z (m); c_p is the heat capacity of air ($\sim 1,003\ kJ\ kg^{-1}\ K^{-1}$); λ is the latent heat of vaporization ($\sim 2.45 \times 10^6\ J\ kg^{-1}$); ρ_w is the density of water ($\sim 1,000\ kg\ m^{-3}$); and ρ_a is air density ($kg\ m^{-3}$, $\rho_a \approx 1.291 - 0.00418T_a$). When R_n , G , T_s , T_a , h_c , and u_z are measured in the field, Equation 6 can estimate ET with fair accuracy (Kimball et al., 1999) for full-cover crop surfaces. Because energy balance models have more numerous applications besides cropped surfaces or irrigation management, they have been investigated more extensively compared with the VI-based crop coefficient approach.

Remote sensing approaches to FSEB evaluation for ET are numerous and include both single-surface approaches that assume that the crop can be modeled as a big leaf (i.e., Equation 6) (e.g., Bastiaanssen et al.,

2005; Allen et al., 2007a, b) and two-surface approaches that evaluate the energy and water balances for both canopy and soil surfaces and thus must estimate the crop cover fraction (e.g., Evett and Lascano, 1993; Norman et al., 1995; Kustas and Norman, 1999; Colaizzi et al., 2012). While providing useful knowledge of regional ET and its spatial and temporal distribution, FSEB predictions that rely on satellite images are not used for irrigation management due to lack of daily data with sufficient resolution to match the field scales at which irrigation is managed (Gowda et al., 2008). Attempts to resolve this problem with existing satellite data involve using infrequent, higher-resolution data such as that from Landsat (90 m resolution in the thermal IR, 16 day repeat time) in combination with lower-resolution more frequent data such as that from MODIS (1,000 m resolution in the thermal IR, daily). Such a combination was demonstrated with the DisALEXI (disaggregated atmosphere land exchange inverse) model (Anderson et al., 2007; Kustas et al., 2007; Norman et al., 2003), but no testing of this approach for irrigation management has ensued. While aircraft platforms could resolve some of these problems, so far there has not been widespread use of aircraft platforms to provide imaging for irrigation management, probably due to cost.

The FSEB using remotely sensed data typically provides an instantaneous value of ET , which must be scaled to daily ET using various methods such as the evaporative fraction (which is assumed constant during daylight hours) or reference ET (which is also assumed constant relative to latent heat flux during daylight hours) (Colaizzi et al., 2006). Models of the FSEB that use remote sensing include the two-source model (TSM, Norman et al., 1995; Kustas and Norman, 1999), the surface energy balance algorithm for land (SEBAL, Bastiaanssen et al., 1998), and mapping ET with internalized calibration (METRIC, Allen et al., 2007a, b). Gowda et al. (2008) reviewed these and several other approaches and reported that daily ET estimation errors ranged from 3 % to 35 % but that almost all studies compared FSEB ET with ET sensed by Bowen ratio or eddy covariance methods, which themselves have large errors. Colaizzi et al. (2012) evaluated the two-source energy balance model of Norman et al. (1995) and Kustas and Norman (1999) where crop ET was measured with weighing lysimeters at Bushland, Texas, and radiometric temperature was measured with infrared thermometers that viewed the lysimeter surface. Crops included fully irrigated corn, alfalfa, soybean, and winter wheat; deficit-irrigated cotton; and dryland grain sorghum. This study differed from previous two-source energy balance model testing studies, which mainly used Bowen ratio or eddy covariance systems to indirectly estimate ET and used remotely sensed data from satellite or airborne platforms to run the models. The root mean squared errors between modeled and observed energy fluxes were slightly greater in the Colaizzi et al. (2012) study compared with the previous studies, which was probably related to the

methods used to estimate ET and radiometric surface temperature.

The vast majority of energy balance model testing studies have been at the watershed or regional scale and used satellite data, which are too coarse and/or infrequent for irrigation management. Moreover, ET estimates from regional models are often inaccurate due to problems with correctly estimating the surface radiation balance components (Berbery et al., 1999). However, several studies, using either ground-based or airborne sensor platforms to achieve suitable spatial scales (i.e., a few meters or less), have shown the utility of energy balance and stress index models for irrigation management (Colaizzi et al., 2003; French et al., 2007), including automatic irrigation scheduling and control (Evelt et al., 1996, 2000, 2006a; Peters and Evelt, 2008). One outcome of the years of research on remote sensing using satellite platforms has been the cross-fertilization of the irrigation engineering field where ground-based sensor platforms are more likely to be utilized but where the principles of remote sensing are just as applicable. Ground-based or near-surface remote sensing provides data of high temporal and spatial resolution that can be very useful in irrigation management, but largely without the need for correction for interference from the atmosphere. Remote sensing principles and techniques are routinely used, including spectral data acquisition and processing, VI relationships to plant cover and condition, thermal infrared data acquisition, relationships to plant condition, and energy balance.

In addition to the main avenues of research and application involving remote sensing for irrigation management, there are some areas that have not seen serious or successful efforts due to either intractable problems, newness of the approach, or lack of direct applicability. Several researchers have documented relationships between surface soil water content or soil profile water content and temperature indices. Sadler et al. (2000) found that the canopy-air temperature difference, ($T_c - T_a$), explained 60 % of the variation of the fraction of available water in the top meter of soil. Colaizzi et al. (2003) developed relationships between the CWSI of flood-irrigated cotton on a sandy loam with a soil water stress index and with both the fractional soil water content depletion and depth of depletion. However, they stressed that the relationship was strongest for severely depleted soil and water-stressed plants and would lose relevance for frequently and more adequately irrigated crops. Passive and active microwave radiation and synthetic aperture radar have been used for surface water content estimation (top few centimeters of soil) but encounter the problems of imprecisely known sensing depth, interference from vegetation, and spatial resolution too coarse for irrigation management. Characterization of soil roughness needed to produce accurate soil water content estimates is not well understood, and only regional-scale mapping is possible (Verhoest et al., 2008). A series of field campaigns with various types of ground truthing have explored this and related approaches

to soil water content sensing (Washita'92, Washita'94, SGP97, SGP99, SMEX02, SMEX03, SMEX04, SMEX05, CLASIC – Land, SMAPVEX08; e.g., Jackson et al., 1995, 1999, 2005, 2008; Jackson and Hsu, 2001). This approach is more useful for synoptic studies than for irrigation management (e.g., Zhan et al., 2008). Some recent work has focused on using thermal remote sensing surface temperature data as input to a FSEB model with a soil water component in order to drive estimates of profile water content (Crow et al., 2008). This is similar to attempts made using near-surface remote sensing of canopy temperatures to drive models of the soil-plant-atmosphere continuum. To date, these approaches have not been useful in field-scale irrigation management.

Current obstacles

Remotely sensed data must meet several criteria to be suitable for irrigation management, but present satellite and airborne platforms do not meet one or more of these requirements, which include spatial resolution, repeat frequency (i.e., temporal resolution), accuracy, and turnaround time. Jackson (1984) discussed these requirements and concluded that spatial resolution must be on the order of a few meters, repeat frequency no more than a few days (although hourly would be most desirable), and turnaround time (i.e., the interval from actual field measurements to the usable data product) no more than a few minutes. Since then, irrigated area under moving and drip irrigation systems has greatly increased (e.g., >80 % in the Southern Great Plains), and these systems require data at intervals not greater than a day. Present satellite platforms with thermal bands have a trade-off between spatial and temporal resolution. Although satellite data have been successfully used to construct spatially distributed ET maps at the watershed (Allen et al., 2007b) or continental scale (Kustas et al., 2004), they lack adequate spatial resolution for irrigation management and have turnaround times on the order of weeks or more due to extensive processing requirements (i.e., atmospheric and geometric correction). Sharpening algorithms, such as TsHARP, do not accurately recover information at sub-field scales suitable for irrigation management (Agam et al., 2007, 2008). Airborne platforms can potentially meet both the spatial and temporal requirements but are cost prohibitive and also suffer from undue turnaround times because automated processing algorithms have yet to be developed. Moran (1994) demonstrated the shortcomings of both satellites and aircraft for irrigation management, which were mainly due to turnaround time, but also due to inexplicable lapses in data delivery from cooperating entities. More recently, there have been efforts to adopt unmanned air vehicles (UAVs) to carry sensors suitable for on-farm management applications (Herwitz et al., 2004; Xiang and Tian, 2007; Chao et al., 2008). Unresolved issues include the need to reduce sensor package mass, reliable radio control, lack of control

in windy conditions, orthogonal correction of non-nadir views, and geo-referencing.

Rigorous FSEB model assessment and testing is contingent on both accurate ground truth and remotely sensed data. High-quality ground truth data are particularly expensive and difficult to obtain, and the simultaneous acquisition of remotely sensed data is indeed challenging. These factors have impeded development of more robust models. Weighing lysimeters are the most direct and potentially accurate method of ET measurement (Howell et al., 1995); however, they are expensive, not portable, and require highly trained personnel to operate and maintain. ET may also be derived with good accuracy as the residual of the soil water balance if measurements of irrigation, rainfall, and soil water throughout the profile are available, and provided other sources and sinks that are difficult to measure can be minimized or eliminated (e.g., run-on, runoff, deep percolation, and upward capillary flux from a shallow water table). However, accurate measurement of the soil profile water content has been limited to destructive and labor-intensive gravimetric sampling or the neutron moisture meter (NMM), which is also labor intensive and cannot be operated unattended. Electromagnetic soil water sensors presently on the market, which are appealing in that they may be automated, suffer from very poor accuracy in most soils (Evetts et al., 2006b, 2008, 2009; Mazahreh et al., 2008). Other techniques of estimating ET include Bowen ratio, eddy covariance, and meteorological flux towers. These systems are portable, relatively low cost, and easily automated, and hence have been the most popular ground truth techniques for model testing (validation) studies. However, the Bowen ratio method assumes that the conductivity for water vapor flux, K_v , equals the conductivity for heat flux, K_h , and is therefore subject to errors during advective conditions and can also be sensitive to fetch and instrument bias (Todd et al., 2000). Eddy covariance techniques sense turbulent fluxes across a field directly, but the energy balance is often not closed (Evetts et al., 2012a; Twine et al., 2000) even when additional procedures or corrections are used. Meteorological flux towers have been used extensively in desert environments (Kustas and Norman, 1999), but their accuracies over cropped surfaces or in advective environments are presently not known. At present, the most accurate ground truth is from weighing lysimeters and soil water balance ET estimates made using the NMM. Unfortunately, most FSEB model validation efforts have not been able to use those methods. A recent example of using weighing lysimeter and soil water balance measures of ET is, however, available in a special issue of *Advances in Water Resources* (Evetts et al., 2012b).

Ground-based sensors aboard farm machinery, such as self-propelled irrigation systems, are an alternative to satellite or airborne platforms. In regions where center pivot or lateral-move irrigation systems are popular, they appear to be a logical sensor platform for irrigation management, since they pass over the field at regular

intervals. Ground-based sensors may greatly reduce turnaround time because they do not require extensive processing such as atmospheric or geometric correction. Phene et al. (1985) is an early example of deployment of infrared thermometers aboard a self-propelled irrigation system. However, thermal radiometric sensors are responsive to soil emittance and to reflection from vegetative canopy: Less than full canopy cover may cause false-positive irrigation triggers in the early growing season and thermal measurements from mixed pixels of sunlit soil and vegetation can provide unduly high temperature readings. Discrimination between thermal radiance from soil and vegetation in low cover or leaf area index situations is a problem still under active investigation, and solution will probably require imaginative combination of multispectral data, sensor view angles, and understanding of canopy and soil characteristics.

Center pivot and linear move irrigation systems generally apply water quite uniformly; however, substantial variations in soil properties and water availability exist across most fields. In these cases, the ability to manage site-specific irrigation to match spatially and temporally variable conditions can offer opportunities for increased application efficiencies, reduced environmental impacts, more effective agrichemical use, and the potential to improve crop yields and quality. In addition, these types of systems afford the opportunity to precisely manage deficit irrigation strategies. The development of in-field sensor-based control of site-specific applications of water and water-soluble nutrients through the irrigation system offers an effective means to implement site-specific technologies, but the seamless integration of sensors, irrigation control, data interface, software design, and communication at costs that are in balance with the profit advantages of site-specific applications is challenging.

Several researchers have investigated the potential use of a feedback from wireless in-field sensing systems to control variable-rate irrigation systems, but few have fully integrated these systems. An exception is the TTTI system implemented for automatic irrigation control of drip and center pivot irrigation (Evetts et al., 2006a; Peters and Evetts, 2008). Miranda et al. (2003) used a closed-loop irrigation system and determined irrigation amount based on distributed soil water measurements. Shock et al. (1999) used radio transmission for soil moisture data from data loggers to a central computer logging site. Wall and King (2004) explored designs for smart soil moisture sensors and sprinkler valve controllers to implement plug-and-play technology and proposed architectures of distributed sensor networks for site-specific irrigation automation (King et al., 2000). Kim et al. (2008, 2009) used distributed sensor networks and GPS with Bluetooth® wireless communications to control water applications with off-site computers. Software design for automated irrigation control has been studied by Abreu and Pereira (2002). They designed and simulated solid set sprinkler irrigation systems by using software that allowed the design of a simplified layout of the irrigation system.

The coordination of control with data from sensors is effectively managed using data networks and low-cost microcontrollers (Wall and King, 2004). A hardwired system from in-field sensing station to a base station requires extensive time and cost to install and maintain. It may not be feasible to get the system hard wired for long distances, and it may not be acceptable to growers because it can interfere with normal farming operations and the maintenance costs may be unacceptable. A wireless data communication system can provide dynamic mobility and cost-free relocation. Radio frequency technology has been widely adopted in consumer wireless communication products, and it provides numerous opportunities to use wireless signal communication in agricultural systems. Industrial wireless standards such as the ZigBee protocol are open standards that allow integration of sensors and equipment from different manufacturers into a supervisory control and data acquisition (SCADA) system (O'Shaughnessy and Evett, 2007, 2008). Present challenges include meeting power requirements of remote sensors, radio interference, cost reduction, interfacing with existing irrigation control equipment, and development of rugged and inexpensive but accurate sensors (e.g., reflectance photodiodes and infrared thermometers).

Importance of unified technologies

Inherent in the evolution of on-farm water management is the integration of irrigation, fertilizer, and pest management strategies into systems that optimize total management practices for temporal and spatial variability using precision agriculture tools. This integration will require broad systems approaches that physically and biologically optimize irrigations with respect to water delivery and application schemes, rainfall, critical growth stages, soil fertility, location, and weather. Spatial and temporal management strategies will need to address site-specific crop requirements for water, nutrition, pest management, and irrigation scheduling in both agrarian and urban settings.

Improved irrigation technologies, while usually requiring less field labor, often demand more intensive management. Thus, support aids must also be developed that improve the producer's ability to implement decisions quickly and easily; however, this also requires control and monitoring systems. Decision support systems are needed to help make timely decisions based on complex inputs. Climatic variations and pest outbreaks require precisely timed and placed water and chemical applications on a daily and seasonal basis. The decision support process must also provide accurate predictions of crop water use, application efficiencies, and uniformities to improve management flexibility.

The commercialization of irrigation automation is dependent on the development of economical and reliable wireless sensors and sensor networks. Communication modules for each sensor type and network must be interchangeable. The progress of precision irrigation depends

on the seamless automatic operation of irrigation systems accomplished by the flexible integration of controllers and sensors, algorithms for data acquisition and control, compatible sensor hardware that is field installable and easy to maintain (plug-and-play format), and user-friendly interfaces that provide practical, robust, and timely decision-making support to the grower.

Conclusions

Ensuring the success of irrigated farming enterprises will require the development of reliable, timely information on field and plant status to support decision making. Remote sensing of plant and soil status using integrated satellite, aerial, and field-level plant and soil-based sensor systems can provide information on plant and soil nutrient and water status. Nevertheless, this technology needs further development to improve spatiotemporal modeling and hands-on use for on-farm management as well as irrigation district operations. Better systems and methods capable of measuring specific plant parameters (e.g., nutrient status, water status, disease, and competing weeds) on a timely basis are becoming available and are expected to provide information required to enhance use in crop modeling and improve within-season management.

Several remote sensing approaches have been shown to provide spatially distributed information on ET and plant water stress that is meaningful for irrigation management. These approaches use reflectance and thermal radiance measurements of the surface; those discussed herein included water stress indices, vegetation index (VI)-based crop coefficients, and surface energy balance models. Water stress indices are generally used to detect plant water stress and may be useful for appropriately timing irrigation events. The VI-based crop coefficient approach can be used to estimate crop ET when a reference ET value is available. This approach is essentially the same as the widely used crop coefficient-reference ET paradigm, where crop coefficients are based on calendar days or heat units, but VI-based crop coefficients estimated from images provide spatial information of actual crop conditions, unlike conventional crop coefficients. Surface energy balance models are generally classed as either single-layer or two-layer approaches, where the latter computes the energy fluxes of the soil and vegetation separately. Both types of energy balance models compute instantaneous latent heat flux, which can be converted and scaled to daily ET. The VI-based crop coefficient approach requires reflectance measurements but not thermal measurements as do water stress indices and energy balance models. However, the VI-crop coefficient approach is more empirically based and subject to local conditions, which may reduce geographic transferability. Energy balance models have been researched more extensively than VI-based crop coefficients, as they are applicable to other vegetated surfaces besides crops.

Routine application of remote sensing to irrigation management remains subject to several obstacles, which are generally related to model robustness and sensor platform cost, timeliness, and spatial resolution. The development of robust models has been hampered somewhat by inherent challenges in measuring ET or plant water stress for ground truth while simultaneously measuring surface reflectance and temperatures. The need for accurate and robust models is critical if they are to provide meaningful decision support for the rational allocation and timing of irrigation water. Just as critical is a fundamental understanding of model limitations, so that misapplication may be avoided. Sensor platforms, in order to be suitable for irrigation management, must provide data at spatial resolutions of a few meters, at least daily repeat frequencies, and have turnaround times of a few minutes. Existing satellite and airborne platforms do not meet one or more of these criteria. Key satellite platforms for thermal infrared data with sufficient spatial (but not temporal) resolution for irrigation management (LandSat 5 and 7) are nearing the end of their useful lives, and there is no near-term replacement, which makes expediting of the only new satellite planned with thermal IR capability (HypIRI, with 45 m resolution and a 5 day cycle) essential (Anderson and Kustas, 2008). Unmanned air vehicles (UAVs) and ground-based sensors aboard self-propelled irrigation systems have the potential to avoid some of the pitfalls of satellite or airborne platforms but nonetheless have other technical and cost issues to be overcome. At a time when thermal infrared data from satellite remote sensing is finally being used for effective water resource management at large scales (Allen et al., 2008), and when the technology for managing irrigation at small scales is becoming well developed and would be applicable if resolution in time and space were improved, the USA should be highly motivated to, rather than end its efforts, become once again a leader in space-based platforms for thermal infrared imaging at high spatial and temporal resolution.

Irrigated agriculture will be expected to provide more crops for a growing world population with less water resources. Also, farm consolidation continues in many regions, resulting in greater area being managed by fewer personnel. The need for better irrigation management tools that reduce management time is apparent. Remote sensing, with its capabilities of spatially distributed information, is one technology that may fulfill this need. Therefore, research and development efforts should continue to emphasize model validation and refinement and more suitable platforms and sensors capable of delivering timely irrigation management guidance and control at scales small enough to affect within-field management.

L

LAND SURFACE EMISSIVITY

Alan Gillespie
Department of Earth and Space Sciences, University
of Washington, Seattle, WA, USA

Definitions

Land surface emissivity (LSE). Average emissivity of an element of the surface of the Earth calculated from measured radiance and land surface temperature (LST) (for a complete definition, see Norman and Becker, 1995).

Atmospheric window. A spectral wavelength region in which the atmosphere is nearly transparent, separated by wavelengths at which atmospheric gases absorb radiation. The three pertinent regions are “visible/near-infrared” ($\sim 0.4\text{--}2.5\ \mu\text{m}$), mid-wave infrared ($\sim 3\text{--}5\ \mu\text{m}$) and long-wave infrared ($\sim 8\text{--}14\ \mu\text{m}$).

Blackbody. An ideal material absorbing all incident energy or emitting all thermal energy possible. A cavity with a pinhole aperture approximates a blackbody.

Brightness temperature. The temperature of a blackbody that would give the radiance measured for a surface.

Color temperature. Temperature satisfying Planck’s law for spectral radiances measured at two different wavelengths.

Contrast stretch. Mathematical transform that adjusts the way in which acquired radiance data translate to the black/white dynamic range of the display monitor.

Emissivity ε . The efficiency with which a surface radiates its thermal energy.

Irradiance. The power incident on a unit area, integrated over all directions (W m^{-2}).

Graybody. A material having constant but non-unity emissivity.

Long-wave infrared (LWIR). For most terrestrial surfaces ($\sim 340\ \text{K}$ to $\sim 240\ \text{K}$), peak thermal emittance occurs in the LWIR ($\sim 8\text{--}14\ \mu\text{m}$).

Mid-infrared (MIR). Forest fires ($\sim 1,000\text{--}600\ \text{K}$) have peak thermal emittances in the MIR ($\sim 3\text{--}5\ \mu\text{m}$).

Noise equivalent Δ temperature ($NE\Delta T$). Random measurement error in radiance propagated through Planck’s law to give the equivalent uncertainty in temperature.

Path radiance $S_{\uparrow}$. The power per unit area incident on a detector and emitted upward from within the atmosphere ($\text{W m}^{-2}\ \text{sr}^{-1}$).

Planck’s law. A mathematical expression relating spectral radiance emitted from an ideal surface to its temperature (Equation 1, in the entry *Land Surface Temperature*).

Radiance. The power per unit area from a surface directed toward a sensor, in units of $\text{W m}^{-2}\ \text{sr}^{-1}$.

Reflectivity ρ . The efficiency with which a surface reflects energy incident on it.

Reststrahlen bands. Spectral bands in which there is a broad minimum of emissivity associated in silica minerals with interatomic stretching vibrations of Si and O bound in the crystal lattice.

SEBASS. Spatially Enhanced Broadband Array Spectrograph System, a hyperspectral TIR imager (Hackwell et al., 1996).

Short-wave infrared (SWIR). Erupting basaltic lavas ($\sim 1,400\ \text{K}$) have their maximum thermal emittance at $\sim 2.1\ \mu\text{m}$ in an atmospheric window at $0.4\text{--}2.5\ \mu\text{m}$. Part of this spectral region ($1.4\text{--}2.5\ \mu\text{m}$) is called the SWIR.

Sky irradiance $I_{\downarrow}$. The irradiance on the Earth’s surface originating as thermal energy radiated downward by the atmosphere (W m^{-2}) (spectral irradiance: $\text{W m}^{-2}\ \mu\text{m}^{-1}$).

Spectral radiance L . Radiance per wavelength, in units of $\text{W m}^{-2}\ \mu\text{m}^{-1}\ \text{sr}^{-1}$.

Thermal infrared (TIR). Thermal energy is radiated from a body at frequencies or wavelengths in proportion to its temperature. The wavelengths for which this radiant energy

is significant for most terrestrial surfaces ($\sim 1.4\text{--}14\ \mu\text{m}$) are longer than the wavelength of visible red light and hence are known as thermal infrared. The TIR is subdivided into three ranges (LWIR, MIR, SWIR) for which the atmosphere is transparent (atmospheric “windows”) so that the energy can be measured from space.

Introduction

Thermal emissivity ε is the efficiency with which a surface emits its stored heat as thermal infrared (TIR) radiation. It is useful to know because it indicates the composition of the radiating surface and because it is necessary as a control in atmospheric and energy-balance models, since it must be known along with brightness temperature to establish the heat content of the surface. The first practical demonstration of multispectral TIR imaging for compositional mapping was from a NASA airborne scanner flown over Utah (Kahle and Rowan, 1980).

Emissivity differs from wavelength to wavelength, just as reflectivity ρ does in the spectral region of reflected sunlight ($0.4\text{--}2.5\ \mu\text{m}$). Emissivity is defined as

$$\varepsilon(\lambda) = \frac{L(\lambda, T)}{B(\lambda, T)} \quad (1)$$

where L is the measured spectral radiance and B is the theoretical blackbody spectral radiance for a surface with a skin temperature T . B is given by Planck’s law which, together with the basic physics of TIR radiative transfer, is discussed in the entry *Land Surface Temperature* (LST).

Unlike T , which is a variable property of a surface controlled by the heating history and not directly by composition, $\varepsilon(\lambda)$ is independent of T and is a function directly of composition. Furthermore, $\varepsilon(\lambda)$ in the TIR wavelengths ($3\text{--}14\ \mu\text{m}$) responds to different aspects of composition than reflectivity $\rho(\lambda)$ at $0.4\text{--}2.5\ \mu\text{m}$. In general, ρ at wavelengths $0.4\text{--}2.5\ \mu\text{m}$ is controlled by the amounts of iron oxides, chlorophyll, and water on the surface; ε in the TIR is controlled more by the bond length of Si and O in silicate minerals. Examples of emissivity spectra are given in Figure 1.

TIR spectroscopy is especially important because silicate minerals are the building blocks of the geologic surface of Earth, and their presence and amounts can be inferred only indirectly at shorter wavelengths. Thus TIR spectroscopy is complementary to spectroscopy of reflected sunlight. Good summaries of TIR spectroscopy and its significance in terms of surface composition may be found in Lyon (1965), Hunt (1980), and Salisbury and D’Aria (1992). A good introduction to spectral analysis may be found in Clark et al. (2003).

Figure 1 shows daytime and nighttime false-color composite images of spectral radiance from a sparsely vegetated part of Death Valley, California, enhanced using a decorrelation contrast stretch (Soha and Schwartz, 1978; Gillespie et al., 1986). This stretch emphasizes the emissivity component of the signal, shown as color, and

de-emphasizes the temperature, shown as dark/light intensity. In addition to composition, the daytime image gives a good sense of topography, because sunlit slopes are warmer than shadowed slopes. In the nighttime image, most temperature effects are subdued, and the image closely resembles the Land Surface Emissivity (LSE) alone.

Exceptions include standing water, which is cooler than the land during the day but warmer at night. Standing water (C) in the floor of Death Valley shows dark green in the daytime image but light pink in the nighttime image. Vegetation (A) appears dark in the daytime image, when it is cooling its canopy by evapotranspiration. The toe of an alluvial fan (B) appears darker at night, when soil moisture rises to the surface and evaporates.

The colors in Figure 1 indicate rock type. For example, the emissivity of quartzite is low (~ 0.8) at 8.3 and $9.1\ \mu\text{m}$ (blue and green) but high at $10.4\ \mu\text{m}$ (red); therefore, it is displayed as red. Other rock types and display colors can be understood by comparing the images and emissivity spectra in Figure 1.

The discussion below focuses on algorithms designed to recover emissivities from remotely sensed spectral radiance data. Figure 2, of a desert landscape, compares spectral radiance to temperature and emissivity images recovered from it. Also shown are emissivity spectra of vegetation and the geologic substrate. As explained in the entry *Land Surface Temperature*, temperature and emissivity recovery is an underdetermined problem, and dozens of approaches have been proposed and published that break down the indeterminacy. These fall in four classes: deterministic algorithms that solve for *LST* and *LSE* exactly, algorithms that recover the shape of the LSE spectrum only, model approaches that make key assumptions, and algorithms that attempt also to scale or calibrate the normalized spectra to their actual emissivity values.

In evaluating the algorithms, it is useful to ask how accurately it is necessary to recover LSE and LST. For example, many analytic algorithms that seek to identify surface composition rely not so much on actual emissivity values, but on the central wavelengths of emissivity minima (e.g., reststrahlen bands), which can be diagnostic for many rocks and minerals. If this is your goal, it may not be necessary to scale the spectra, relying instead on the simpler algorithms that just recover spectral shape.

Errors in LST may affect some algorithms by warping the spectra over several μm of wavelength. This happens because the shape of the Planck function changes with temperature (*Land Surface Temperature*, Figure 2). A 5 K error at 300 K, for example, will cause a slope in the recovered emissivity spectrum of 0.05 from 8 to $14\ \mu\text{m}$. However, the sharp mineralogical features ($\sim 0.2\text{--}0.5\ \mu\text{m}$ wide) are readily distinguished against this distorted continuum.

The TIR is commonly a difficult spectral region in which to measure spectral radiance, and the images are typified by a low signal–noise ratio. This ratio is commonly represented by the “noise equivalent Δ temperature” or

Land Surface Emissivity, Figure 1 Airborne thermal infrared multispectral scanner (TIMS: Palluconi and Meeks, 1985) false-color TIR radiance images of Death Valley, California (RGB = 10.4, 9.1, 8.3 μm). Letters A, B, and C indicate sites discussed in the text. *Central column* shows laboratory spectra for field samples. *Inset* shows similar ASTER image “draped” over topography, looking north up Death Valley. The TIMS images cross the central part of the ASTER footprint (Courtesy Harold Lang and Anne Kahle, JPL).

NEAT, which is the temperature difference corresponding to the standard deviation of the radiance within a homogeneous, isothermal scene region. For TIR imagers such as ASTER, $NEAT_{300K} \approx 0.25$ K. Also for ASTER, the NEAT, atmospheric correction, and radiometric calibration all introduce errors of about the same size, leading to a total uncertainty in the recovered LST of about 1.5 K and in the LSE of ~ 0.015 .

Deterministic solutions for emissivity

As discussed in *Land Surface Temperature*, recovering both LST and LSE from a single image is underdetermined. In principle, this problem can be removed by increasing the number of images acquired for the same scene. For each n -channel image, after atmospheric compensation, there are $n + 1$ unknowns, but only n measurements; for two images of the same scene, there are $n + 2$ unknowns, but $2n$ measurements (assuming LST has changed but LSE has remained constant). Therefore, a two-channel image taken at two different times is

deterministic. It is additionally necessary that the LST be significantly different between acquisitions.

Two-time, two-channel approach

If well-registered multispectral day–night radiance measurements are available, it is possible to determine T and ϵ uniquely (Watson, 1992a). Although this approach is esthetic, for most TIR data, the recovered temperatures and emissivities tend to be imprecise. For example, for image channels at 8 and 12 μm , day–night temperatures of 290 and 310 K, and for $NEAT = 0.3$ K, recovered LST would have an uncertainty of ≥ 20 K. This arises because of the flat shape of the Planck curve in the spectral range around 300 K.

Wan (1999) showed that using an image channel in the 3–5 μm window, where the slope of the Planck function is steep, can improve the precision greatly and used the day–night algorithm to make a standard MODIS LST product. However, for daytime data, reflected sunlight at 3–5 μm must be accounted for (see *Land Surface Temperature*, Figure 3). Furthermore, acquiring data 12 h or more apart

Land Surface Emissivity, Figure 2 TIR images and spectra, South Mountain, Arizona, looking SE. (a) Natural color; (b) TIR radiance at 9 μm; (c) brightness temperature; (d) emissivity (RGB = 8, 8.5 and 9 μm, respectively); (e) emissivity spectra measured with the TELOPS, Inc., FIRST hyperspectral imaging spectrometer, August 8, 2007. The shrub spectrum was taken from the site in d marked the green cross; the rock spectrum from the red cross. Differences in the “rock” spectra likely relate to differences in the pixel field of view and exact location, and in the length of the atmospheric path between the sample and sensor.

adds complexity because the scene may have changed between images, for example, because of dew.

It is also advantageous to use more than two channels, in which case the inversion for LST and LSE is overdetermined. This has the advantage of reducing the impact of measurement errors. The exaggeration of measurement error in this otherwise esthetic technique will become less severe as high-precision imagers such as SEBASS ($NEAT_{300K, 11\mu m} < 0.05$ K; Hackwell et al., 1996) become widely available.

Emissivity bounds method

Jaggi et al. (1992) observed that for every pixel and every channel i there exists a locus of (T, ϵ_i) vectors that are possible solutions for the modified Planck equation (Equation 1, *Land Surface Temperature*). Because T must be the same for all image channels, some (T, ϵ_i) pairs can be ruled out as candidate solutions. The range of solutions is even more limited if ϵ and/or T can be restricted a priori. For the land surface, it is commonly possible to assume that $0.8 < \epsilon < 1.0$, for example.

This elegant approach is not truly deterministic, because it requires assumed limits to ϵ and/or T . However, it requires no empirical assumptions. The technique does not appear to have been widely used, perhaps because it does not identify the most probable values of ϵ or T , only possible ranges. In practice, performance depends on

how well emissivity limits are known a priori, and implementation would probably require some sort of image classification to establish them closely.

Spectral-shape solutions

Although it is not possible to invert the modified Planck equation for both ϵ and T without external constraints, it is possible to estimate spectral shape for ϵ , at the expense of T and of the amplitude of the recovered spectrum, that is, the recovered spectra are essentially normalized, so that only relative amplitudes (wavelength to wavelength) are known. This is nevertheless useful, since composition is generally determined from spectral shape, and not the absolute amplitudes.

Ratio methods

Watson (1992b) observed that ratios of spectrally adjacent channels i and j described spectral shape accurately, provided that T could be estimated even roughly:

$$\frac{\epsilon_j}{\epsilon_i} = \frac{L_j \lambda_i^5 (\exp(c_2/(\lambda_i T)) - 1)}{L_i \lambda_j^5 (\exp(c_2/(\lambda_j T)) - 1)} \quad (2)$$

(c_2 is a constant from Planck's law, Equation 1, *Land Surface Temperature*). To calculate the ϵ ratios, it is necessary first to approximate the temperature T from the measured radiances L_i and L_j . If ϵ can be estimated

Land Surface Emissivity, Figure 3 Emissivity $\varepsilon(\lambda)$ and spectral radiance spectra $L(\lambda)$ for basalt at 300 K. $L(\lambda)$ was calculated as the product of measured $\varepsilon(\lambda)$ and a 300 K blackbody ($B(\lambda)$) spectrum. In “Planck draping,” blackbody spectra are calculated for successively lower temperatures (e.g., 310, 305 and 301.5 K, above) until $\varepsilon_{\max} B(\lambda) = L(\lambda)$ at some wavelength. The maximum emissivity, $\varepsilon_{\max}$ must be estimated, usually as a value near 0.95 as in the example shown. $\varepsilon^*(\lambda)$, the recovered $\varepsilon(\lambda)$, is calculated as $L(\lambda)/B(\lambda)$. Both it and the found LST (301.5 K, above) will be inaccurate unless the Planck functions are scaled correctly by $\varepsilon_{\max}$. In the example shown, LST is in error by 1.5 K. The error warps $\varepsilon^*(\lambda)$ slightly.

within ± 0.075 , the uncertainty in T is ± 5 K, and the ε ratios can be estimated with an average error of ~ 0.007 (this estimate does not include the effects of measurement error).

Becker and Li (1990) proposed a similar approach they called the “temperature-independent spectral indices” (TISI) method. TISI begins with the observation (Slater, 1980) that Planck’s law may be represented by

$$B_k(T_s) = \alpha_k(T_o) T^{n_k(T_o)} \quad (3)$$

where B is the spectral radiance in image channel k for a blackbody at temperature T_s and T_o is a reference temperature. Constants n_k and α_k are given by

$$n_k(T_o) = \frac{c_2}{\lambda_k T_o} \left(1 + \frac{1}{\exp(c_2/\lambda_k T_o) - 1} \right); \quad (4)$$

$$\alpha_k(T_o) = \frac{B_k(T_o)}{T_o^{n_k(T_o)}}$$

(Dash, 2005). The land-leaving spectral radiance L_k , corrected for atmospheric absorption and path radiance but not down-welling spectral irradiance $L_k^{\downarrow}$, is thus

$$L_k = \varepsilon_k \alpha_k T_s^{n_k} C_k; \quad C_k = 1 + \frac{(1 - \varepsilon_k) L_k^{\downarrow}}{\varepsilon_k B_k(T_s)} \quad (5)$$

where C_k is spatially variable and atmosphere specific. The TISI is found by rationing spectral radiances for image channels i and j :

$$\frac{L_i^{a_i}}{L_j^{a_j}} = \frac{\varepsilon_i^{a_i} \alpha_i^{a_i} T_s^{n_i a_i} C_i^{a_i}}{\varepsilon_j^{a_j} \alpha_j^{a_j} T_s^{n_j a_j} C_j^{a_j}} \quad (6)$$

Here a_i is defined as n_i^{-1} (and $a_j = n_j^{-1}$), chosen to make Equation 6 independent of T . Since for a wide range of temperatures the C ratio is close to unity, TISI is then

$$TISI_{i,j} = \left[\frac{L_i}{\alpha_i} \right]^{1/n_i} \left[\frac{L_j}{\alpha_j} \right]^{-1/n_j} = \frac{\varepsilon_i^{1/n_i} C_i^{1/n_i}}{\varepsilon_j^{1/n_j} C_j^{1/n_j}} \approx \frac{\varepsilon_i^{1/n_i}}{\varepsilon_j^{1/n_j}} \quad (7)$$

The ratio spectra are insensitive to temperature, for normal terrestrial ranges. The approaches are adaptable for most sensors.

Alpha-residual method

The alpha-residual algorithm produces a relative emissivity spectrum that preserves spectral shape but, like the ratio methods, does not yield actual ε or T values. The alpha residuals are calculated utilizing Wien’s approximation of Planck’s law, which neglects the “ -1 ” term in the denominator. This makes it possible to linearize the approximation with logarithms, thereby separating λ and T :

$$\frac{c_2}{T} \approx \lambda_j \ln(\varepsilon_j) - \lambda_j \ln(L_j) + \lambda_j \ln(c_1) - 5\lambda_j \ln(\lambda_j) - \lambda_j \ln(\pi). \quad (8)$$

Here c_1 and c_2 are the constants defined in Planck’s law (Equation 1, *Land Surface Temperature*) and j is the image channel. Wien’s approximation introduces a systematic error in ε_j of $\sim 1\%$ at 300 K and 10 μm wavelength.

The next step is to calculate the means for the parameters of the linearized equation, summing over the n image channels:

$$\frac{c_2}{T} \approx \frac{1}{n} \sum_{j=1}^n \lambda_j \ln(\varepsilon_j) - \frac{5}{n} \sum_{j=1}^n \lambda_j \ln(\lambda_j) - \frac{1}{n} \sum_{j=1}^n \lambda_j \ln(L_j) + (\ln(c_1) - \ln(\pi)) \frac{1}{n} \sum_{j=1}^n \lambda_j. \quad (9)$$

The residual is calculated by subtracting the mean from the individual channel values. Collecting terms, a set of n equations is generated relating ε_i to L_i , independent of T :

$$\lambda_j \ln(\varepsilon_j) - \mu_\alpha = \lambda_j \ln(\lambda_j) - \frac{1}{n} \sum_{j=1}^n \lambda_j \ln(L_j) + \kappa_i. \quad (10a)$$

$$\kappa_i \approx 5\lambda_i \ln(\lambda_i) - \sum_{j=1}^n \lambda_j \ln(\lambda_j) - (\ln(c_1) - \ln(\pi))(\lambda_j - \bar{\lambda}) \quad (10b)$$

$$\mu_\alpha = \frac{1}{n} \sum_{j=1}^n \lambda_j \ln(\varepsilon_j); \quad \bar{\lambda} = \frac{1}{n} \sum_{j=1}^n \lambda_j \quad (10c)$$

Note that κ_i contains only terms which do not include the measured spectral radiances, L_i , and hence may be calculated from the constants. Although dependency on T has been eliminated, it has been replaced by the unknown μ_α , related to the mean emissivity, such that the total number of unknowns is unchanged. The components of the alpha-residual spectrum vary only with the measured radiances. They are defined as

$$\alpha_i \equiv \lambda_i \ln(\varepsilon_i) - \mu_\alpha \quad (11)$$

and are equivalent to the right-hand side of Equation 10a (α is defined differently than in the TISI method).

Model approaches

In this section, three algorithms distinguished by their model assumptions are described. The most specific requires that both a value of ε and the wavelength at which it occurs be known. The next requires only that the value be known. The third does not require the value of the emissivity to be known, only that the emissivity at two known wavelengths be the same.

The model emissivity (or reference channel) method (Kahle et al., 1980) assumes that the value of ε for one of the image channel's ref is constant and known a priori, reducing the number of unknowns to the number of measurements. First, the temperature is estimated using

$$T = \frac{c_2}{\lambda_{ref}} \left(\ln \left(\frac{c_1 \varepsilon_{ref}}{\pi L_{ref} \lambda_{ref}^5} \right) + 1 \right)^{-1} \quad (12)$$

Lyon (1965) suggested that, for most rocks, the maximum emissivity (ε_{max}) was commonly ~ 0.95 and occurred at the long-wavelength end of the 8–14 μm TIR window. This observation has been used to justify the assumption $\varepsilon_{ref} = \varepsilon_{max}$, typically for $10 < \lambda_{ref} < 12 \mu\text{m}$.

Blackbody spectral radiances B_j for the remainder of the channels are next calculated from T and Planck's law. The model emissivities are $\varepsilon_j = L_j/B_j$.

No single value of ε_{ref} is appropriate for all surfaces. For example, for vegetation, $\varepsilon_{max} \approx 0.983$; if the value is assumed to be 0.95, the emissivities will be underestimated, the spectrum warped, and T overestimated by ~ 2.3 K. Vegetation, snow, and water are all subject to this kind of error. Also, reststrahlen bands for some types of rocks, for example, peridotite, occur near 10 μm , and ε_{max} occurs at shorter wavelengths. For these rock types, the errors may be even greater. Nevertheless, the model emissivity approach is robust and has the virtue of simplicity. It produces reliable results for a wide range of surface materials.

Retaining the assumption $\varepsilon_{ref} = \varepsilon_{max}$ but allowing the reference channel to vary, pixel by pixel, allows the model emissivity approach to be accurate for a wider range of materials. This approach is called the normalized emissivity method (NEM) (Gillespie, 1985; Realmuto, 1990). First, the brightness temperature T_b is found for each image channel, using Planck's law. T_b differs from channel to channel only if ε_j does also, since the actual skin temperature must be the same. The channel j with the maximum T_b is also the channel for which the maximum ε_j occurs and becomes the reference channel. For 81 spectra evaluated by Hook et al. (1992), 58 % of the temperatures found by the NEM algorithm were accurate to within 1 K, compared to only 21 % of temperatures recovered using the model emissivity method.

Finding the maximum T_b has been called the "Planck draping" method (Figure 3). This approach has been used to estimate $\varepsilon(\lambda)$ from high-resolution radiance spectra collected by hyperspectral imagers such as SEBASS or by field spectrometers.

Instead of examining the same scene element at two different times and temperatures, as in the day–night method, the scene element may be measured at different wavelengths λ_i and λ_j , chosen such that $\varepsilon_i = \varepsilon_j$. In such a case, it is necessary to find T (the "color temperature," T_c ; see Equations 10 and 11, *Land Surface Temperature*) and only a single ε for the two channels, and the situation is deterministic (two measurements, L_i and L_j , and the two unknowns, T_c and $\varepsilon_i = \varepsilon_j$). As for the reference channel method, T_c can then be used to calculate a blackbody spectrum B , from which $\varepsilon(\lambda)$ can be found. This treatment has been called the "graybody emissivity method" (Barducci and Pippi, 1996).

The strength of the technique lies in its ability to recover emissivities even if the value of ε is unknown. The main weaknesses are that for imagers with only a few TIR channels, the basic requirement, $\varepsilon_i = \varepsilon_j$, is not met for much of the land surface, and it is not always possible to know λ_i and λ_j . If the assumption is valid, the accuracy for T is comparable to NEM, provided λ_i and λ_j are widely separated (e.g., Mushkin et al., 2005), but for most rock spectra, errors are ≥ 5 K. Barducci and Pippi (1996) proposed the graybody emissivity method for hyperspectral scanners, for which the basic requirement is more likely to be met.

Scaling approaches

Once relative spectra have been calculated, they can be calibrated to "absolute" emissivity provided a scaling factor is known. Applied to the ratio approach of Watson (1992b) or the TISI approach of Becker and Li (1990), this is basically the same as one of the model algorithms. However, scaling can also be done from empirical regression relating the shape of the emissivity spectrum to an absolute value at one wavelength. The regression is typically based on laboratory spectra of common scene components. More complex approaches also are possible: the first example given below combines the "two-channel,

two-time,” and TISI approaches to convert the relative TISI spectra to emissivities.

The hybrid TISI approach requires first that daytime and nighttime MIR and LWIR images be acquired and co-registered and that their TISI ratios be calculated. Essentially, there are four measurements ($L_{MIR,day}$, $L_{LWIR,day}$, $L_{MIR,night}$, and $L_{LWIR,night}$), four unknowns (ε_{MIR} , ε_{LWIR}), and one model assumption (the solar irradiance on the target). The MIR reflectivity is the complement of ε_{MIR} by Kirchhoff's law (for the complete mathematical development, see Dash, 2005). Using widely separated image channels improves the precision of T and ε recovery (e.g., Mushkin et al., 2005).

Alpha-derived emissivity (ADE) method

The ADE method (Kealy and Gabell, 1990; Hook et al., 1992; Kealy and Hook, 1993) is based on the alpha-residual approach. To recover ε_i , μ_α may be estimated via an empirical regression to the variance parameter v_α found for laboratory spectra:

$$v_\alpha = \frac{1}{n-1} \sum_{j=1}^n \alpha_j^2 \quad (13)$$

where α is defined in Equation 11. The best-fitting curves relating μ_α and v_α are of the form $\mu_\alpha = cv_\alpha^{1/x}$, where c and x are empirically determined coefficients ($c = -0.085$, $v_\alpha = 0.40$, and $r^2 = 0.935$ for ASTER).

Once the emissivities have been estimated, the temperature may be calculated using Planck's law. For 95 % of the library spectra, T was recovered within 1.6 K of the correct value, and Hook et al. (1992) showed that 67 % were accurate to within 1 K, compared to 58 % for the NEM.

The key innovation of the ADE approach is to utilize the empirical relationship between the average ε and a measure of the spectral contrast or complexity in order to restore the amplitude to the alpha-residual spectrum. The regression is based on the observation that, for a blackbody, the mean emissivity is unity and the spectral variance is zero. For minerals with reststrahlen bands or other emissivity features, the variance is greater than zero and, of course, the mean is less than unity. In use, the mean is predicted from the variance, which is calculated from the measured radiances.

Temperature–emissivity separation algorithm (TES)

The TES algorithm (Gillespie et al., 1998) uses a variant of the “minimum–maximum difference” or MMD approach of Matsunaga (1994) to scale relative emissivity spectra. TES is used to generate standard T and ε products from ASTER, but it has been generalized for different scanners. TES can work with as few as three channels provided the channel wavelengths are well chosen to capture the range of emissivities in scene spectra.

The MMD algorithm is related to the ADE algorithm, but is simpler. Whereas ADE utilizes the empirical

relationship between the mean emissivity $\bar{\varepsilon}$ and the variance of alpha-residual emissivities, MMD utilizes an assumed linear relationship between $\bar{\varepsilon}$ and the range of the emissivities themselves, represented by the maximum–minimum difference or *MMD*.

The MMD algorithm requires that the ε spectrum be estimated (e.g., using NEM) in order to calculate *MMD*, from which $\bar{\varepsilon}$ is predicted. The apparent spectrum is then rescaled according to this average, T is calculated, and the process is iterated until the change in T is less than the *NEAT*.

TES uses land-leaving spectral radiance and downwelling sky irradiance as input and provides a first guess for T and ε_j using the NEM algorithm. The correction for reflected sky irradiance is

$$L'_j = L_j - \frac{(1 - \varepsilon_j)}{\pi} I_\downarrow \quad (14)$$

where L_j is the ground-leaving spectral radiance, compensated for atmospheric absorption and path radiance, $I_\downarrow$ is the downwelling sky irradiance, and $(1 - \varepsilon_j)$ is the scene reflectivity (Kirchhoff's law). The NEM emissivities are then recalculated from L'_j and normalized:

$$\beta_j = \frac{\varepsilon_j}{\bar{\varepsilon}} \quad (15)$$

MMD is calculated from the β spectrum and used to predict ε_{min} (instead of $\bar{\varepsilon}$, as in the MMD approach), which is used for scaling:

$$\varepsilon_{min} = 0.994 - 0.687 MMD^{0.737}; \quad \varepsilon_j = \beta_j \left(\frac{\varepsilon_{min}}{\beta_{min}} \right) \quad (16)$$

After early 2009, a linear regression ($\varepsilon_{min} = 0.8625 MMD + 0.955$) was used for scaling in TES (Gustafson et al., 2006) in order to improve TES precision for low-contrast spectra in standard ASTER data products. The TES algorithm differs from the MMD approach in using a better estimate of the emissivity and in basing the “absolute” measure of emissivity on ε_{min} rather than $\bar{\varepsilon}$, a difference that results in less scatter of the data about the regressed line and, hence, improved performance (± 1.5 K; $\pm 0.015 \varepsilon$).

Classification-based algorithms

Classification approaches exploit the relationship between composition and ε and/or ρ to estimate ε pixel by pixel in at least one-image channel, generally in order to find T . T can then be used to calculate $\varepsilon(\lambda)$ in the other channels. Approaches that use channels in reflected sunlight (0.4–2.5 μm) require imagers with multiple, co-registered telescopes. They also make the assumption that TIR emissivities and visible–SWIR reflectivities are correlated. In some cases, for example, vegetation or water, the TIR emissivities can be predicted accurately; in others, for

example, many rocks, this assumption is less robust. Nevertheless, simply being able to distinguish rock and/or soil from vegetation can improve accuracy by 1–2 K. As an example, the NDVI approach (see Equation 9, *Land Surface Temperature*) makes use of co-registered visible red ($\sim 0.65 \mu\text{m}$) and near-infrared (NIR: $0.7\text{--}1.2 \mu\text{m}$) daytime image channels in order to recognize pixels that have a significant fraction of vegetation.

Conclusions

Only a fraction of published temperature–emissivity separation algorithms have been discussed here. (For an alternative summary, see Dash (2005).) Increasingly sophisticated approaches are being devised to improve on old treatments, for example, by using neural net technology to tune algorithms (e.g., Mao et al., 2008; Liang, 1997). However, the basic categories discussed above still apply.

For the most part, calibration inaccuracies, measurement uncertainty, and inaccurate atmospheric characterization all contribute to errors in the recovered LST and LSE. These errors are commonly as large as or larger than those attributable to the algorithms themselves, at least for the high-resolution imagers commonly used for Earth-surface studies. Therefore, algorithms themselves are now not the dominant factor limiting recovery accuracy. However, the next few years may see the introduction of a new generation of sensors, such as SEBASS, with dramatically improved measurement characteristics. In this case, atmospheric compensation may become the biggest source of uncertainty and deserving of attention. Likewise, the performance of some algorithms like the “two-time, two-channel” algorithm that now are strongly limited by measurement precision may improve relative to those algorithms that are limited by different factors, such as TES with its empirical regression of $\varepsilon_{\min}$ and MMD .

LAND SURFACE ROUGHNESS

Thomas Farr

Technology, Pasadena, CA, USA

Synonyms

Microrelief; Microtopography

Definition

Surface roughness is usually defined at the human scales of centimeter to a few meter; larger scales are usually considered as topography. Relief at these scales is familiar to field geologists working at the outcrop scale and those interested in interpretation of landforms and earth-surface processes that form and modify them.

Scientific usefulness

One important surficial geologic process is aeolian erosion, transport, and deposition of sediments. The shear stress wind produces at the earth's surface is strongly affected by the surface roughness. The aerodynamic roughness

parameter, z_0 , depends on the wind speed profile as a function of height about the ground (Greeley et al., 1997). This parameter is used by geologists interested in aeolian processes as well as climatologists seeking to quantify atmospheric coupling with the solid earth.

Windblown dust and sand can also modify surface roughness by mantling and attenuating surface roughness (Farr, 1992; Arvidson et al., 1993). This can lead to estimates of relative age for surfaces such as lava flows or alluvial fans exposed to the same rate of aeolian deposition (Farr, 1992; Farr and Chadwick, 1996).

Streambed and ocean-bottom roughness also affect the flow and transport capabilities of water in those environments (e.g., Butler et al., 2001).

Other geologic processes produce or modify surface roughness, in particular volcanic eruptions which may mantle surfaces with ash or produce new roughness elements through extrusion of lava flows which can be relatively smooth pahoehoe or extremely rough aa. Roughness of lava flows can provide information on their eruption characteristics, such as rate and temperature (e.g., Lescinsky et al., 2007).

Land surface roughness strongly affects many remote sensing techniques. Observations of reflected visible-near-infrared wavelengths are affected by sub-resolution self-shadowing of roughness elements. Thus, rougher surfaces are darker, and the shadows are illuminated by sky light or reflections from adjacent land, shifting the spectral signature of the surface (Adams and Gillespie, 2006). At thermal infrared and microwave wavelengths, which are dominated by emission from solar-heated surfaces, roughness as well as larger-scale topography affects the initial heating of the surface while roughness also affects the efficiency of emission (Ulaby et al., 1982). Active microwave (radar) systems image surfaces through scattering of a transmitted wave from the surface. Smooth surfaces at the scale of the wavelengths, which are typically centimeter-meter, reflect energy away from the receiving antenna and are imaged as dark surfaces, while rough surfaces scatter the incident energy in all directions and show up in bright tones on radar images (Henderson and Lewis, 1998).

Much work has gone into quantitative models which seek to remove the effects of roughness on sub-resolution shadowing and thermal heating and emission (Tsang et al., 2000; Adams and Gillespie, 2006). In the radar area, inversion models have been developed which estimate the surface roughness from radar observations at different angles, polarizations, and wavelengths (Ulaby et al., 1982; Van Zyl et al., 1991; Evans et al., 1992; Dubois et al., 1995; Tsang et al., 2000).

Quantifying surface roughness

Good reviews of techniques for describing quantitatively surface roughness can be found in Dierking (1999), Thomas (1999), Shepard et al. (2001), and Campbell (2002), Chap. 3. The simplest description of surface

roughness is an estimate of the standard deviation (or root-mean square: RMS) of the surface heights (Table 1).

Describing the roughness of a surface by its RMS height leaves out any description of the scales of the

Land Surface Roughness, Table 1 Measures of surface roughness for two natural surfaces. aa is a rough lava flow surface at Pisgah lava field in the Mojave Desert. Playa is a smooth dry lake surface at Lunar Crater volcanic field in central Nevada. Profiles were measured at 1 cm spacing

		aa	Playa
RMS height (cm)		9.8	1.9
Correlation length (cm)		26	46
Power spectrum	Slope	-2.19	-2.24
	Offset	-1.69	-3.45

roughness. One way to describe the scale of the roughness is to calculate the correlation length of profiles. Correlation length is a measure of how quickly heights change when moving along a profile. The autocorrelation function for a surface profile is calculated by sequentially stepping the profile across a stationary copy, multiplying, and normalizing. The autocorrelation is unity for 0 steps, or lags, and then drops as the number of lags increases (Figure 1). The rate of the drop-off, measured by the lag at which the autocorrelation value drops to $1/e$, is called the correlation length, l . Smoother surfaces tend to have larger correlation lengths (Ulaby et al., 1982; p. 822).

Another way to describe quantitatively both the amplitude and scale of surface roughness is through the power spectrum, or power spectral density, usually of profiles. The power spectrum is basically the Fourier

Land Surface Roughness, Figure 1 Profiles and surface roughness measures of two natural surfaces: an aa lava surface (*rough*) and a playa surface (*smooth*). (a) Profiles: aa profile has been offset 20 cm for clarity. (b) Autocorrelation functions for the two profiles. Note rapid drop-off of aa autocorrelation. Horizontal line is at $1/e$. (c) Power spectra of the two profiles. Note they are nearly linear (in log-log plot) and parallel. Playa has much less power at all spatial frequencies.

transform of the profile (or two-dimensional microtopography) (e.g., Bendat and Piersol, 1986; Brown and Scholz, 1985; Austin et al., 1994). This produces a plot showing power, or variance, as a function of spatial frequency or scale (Figure 1). When plotted in log-log coordinates, the functions are found to be approximately linear (e.g., Berry and Hannay, 1978; Farr, 1992; Shepard et al., 2001), indicating a power-law relationship between roughness and scale. This relationship simplifies the quantitative description of the power spectrum of a profile to two numbers: the slope and offset (Table 1). Power spectrum slope is a measure of self-similarity and is related to fractal dimension of a profile, D , by (Brown, 1985):

$$D = \frac{5 + \text{slope}}{2}$$

Power spectrum offset is a measure of overall roughness, sometimes called “roughness amplitude” (Huang and Turcotte, 1989, 1990; Goff, 1990).

Measurement of surface roughness

Measurement of surface roughness at scales of centimeter to several meters is difficult, especially as the area covered must be large enough to make statistically significant calculations of quantities described above for natural surfaces. This usually means measuring an area or profiles 10–20 m or more in size. Techniques used to date include templates (Shepard et al., 2001); stereophotogrammetry from handheld and balloon-borne cameras and from a helicopter (Wall et al., 1991; Farr, 1992); and more recently ground-based lidar systems (Morris et al., 2008). All of these techniques have provided cm or better resolution, but helicopter stereophotogrammetry and ground-based lidar have provided the best coverage.

Summary

Land surface roughness at scales of centimeter to several meters is important in several areas of earth science as well as in the interpretation of remote sensing data. Roughness can be quantified in a variety of ways, but power spectral analysis is best at describing roughness and its scaling properties.

LAND SURFACE TEMPERATURE

Alan Gillespie
 Department of Earth and Space Sciences, University of
 Washington, Seattle, WA, USA

Definition

Land surface temperature (LST). Average temperature of an element of the exact surface of the Earth calculated from measured radiance (for a complete definition, see Norman and Becker, 1995).

Blackbody. An ideal material absorbing all incident energy or emitting all thermal energy possible. A cavity with a pinhole aperture approximates a blackbody.

Color temperature. Temperature satisfying Planck's law for spectral radiances measured at two different wavelengths: for a gray body (this entry), for any emitter, or the blackbody temperature for which visual color is the same as some other source (e.g., in photography).

Emissivity ϵ . The efficiency with which a surface radiates its thermal energy.

Irradiance. The power incident on a unit area, integrated over all directions (W m^{-2}).

Longwave infrared (LWIR). For most terrestrial surfaces (340–240 K) peak thermal emittance occurs at LWIR (8–14 μm).

Mid-infrared (MIR). Forest fires (1,000–600 K) have peak thermal emittances in the MIR (3–5 μm).

MODTRAN. A computer code package that describes the generation and transmission of energy in the Earth's atmosphere. MODTRAN can be used to predict τ , $S_{\uparrow}$, and $I_{\downarrow}$ for terrestrial remote sensing (Berk et al., 2005).

Path radiance $S_{\uparrow}$. The power per unit area incident on a detector and emitted upward from within the atmosphere ($\text{W m}^{-2} \text{ sr}^{-1}$).

Radiance. The power per unit area from a surface directed toward a sensor, in units of $\text{W m}^{-2} \text{ sr}^{-1}$.

Reflectivity ρ . The efficiency with which a surface reflects energy incident on it.

Shortwave infrared (SWIR). Erupting basaltic lavas (1,400 K) have their maximum thermal emittance at 2.1 μm in a third atmospheric window (0.4–2.5 μm). Part of this spectral region (1.4–2.5 μm) is called the SWIR.

Sky irradiance $I_{\downarrow}$. The irradiance on the Earth's surface originating as thermal energy radiated downward by the atmosphere (W m^{-2}).

Spectral radiance L . Radiance per wavelength, in units of $\text{W m}^{-2} \mu\text{m}^{-1} \text{ sr}^{-1}$.

Thermal infrared (TIR). Thermal energy is radiated from a body at frequencies or wavelengths in proportion to its temperature. The wavelengths for which this radiant energy is significant for most terrestrial surfaces (1.4–14 μm) are longer than the wavelength of visible red light and hence are known as thermal infrared. The TIR is subdivided into three ranges (LWIR, MIR, and SWIR) for which the atmosphere is transparent (atmospheric “windows”) so that the energy can be measured from space.

Transmissivity τ . The efficiency with which a material transmits energy incident on it.

Introduction

Temperature is a fundamental property of the Earth's surface that can be determined remotely. At all spatial scales, temperature is used in energy-balance and ecological studies, and it is important for geothermal and volcanic monitoring. At fine scales, temperature images are used to identify “hot spots” in fighting fires. Recently, they have been important for monitoring the seasonal onset of melting and freezing conditions in the Arctic, where melting is anticipated to occur earlier, and freezing later, as “global warming” worsens.

The land surface temperature (LST) itself is not measured directly from airborne or spaceborne sensors. Instead, the surface radiates thermal energy in the thermal infrared (TIR) part of the spectrum. The energy is radiated in proportion to temperature; therefore, the temperature can be calculated from it.

Temperature is variable at all temporal scales, but diurnal and seasonal fluctuations are perhaps the most noticeable. Figure 1 compares day-and nighttime TIR images of the same scene, the summit of Mauna Loa, Hawaii. The daytime image is dominated by cooling due

Land Surface Temperature, Figure 1 TIR radiance images of the caldera of Mauna Loa volcano, Hawaii. Satellite images from the multispectral thermal imager (MTI), acquired at $8.65 \mu\text{m}$ 10/09/00 (day) and 10/12/00 (night).

Land Surface Temperature, Figure 2 The spectrum of emitted spectral radiance for surfaces at different temperatures (note logarithmic scale on y-axis). Most terrestrial remote sensing is for surfaces between 340 and 240 K (shaded area). The peak spectral radiance occurs at longer wavelengths for cooler surfaces, but at any given wavelength it rises exponentially with temperature.

to topographic shading and thermal inertia of the lavas. Darker surfaces absorb more sunlight and so will be warmer. At night, the topographic effects are minimal, and white fractures in the lava (70°C) delineate zones of geothermal heat rising within the caldera.

The basic equation governing relationship of surface or “skin” temperature and radiant energy is Planck’s law (Figure 2):

$$B(\lambda, T) = \frac{c_1}{\pi \lambda^5} \left(\exp\left(\frac{c_2}{\lambda T}\right) - 1 \right)^{-1} \quad (1)$$

where B is the spectral radiance ($\text{Wm}^{-2} \mu\text{m}^{-1} \text{sr}^{-1}$) at wavelength λ (μm) and temperature T (K) and $c_1 = 3.7418 \cdot 10^{-16} \text{ Wm}^2$ and $c_2 = 14,388 \mu\text{m K}$. It is assumed that the surface emits equally in all directions.

Integrating Equation 1 across all wavelengths gives the Stefan-Boltzmann law

$$j = \frac{\sigma}{\pi} T^4 \quad (2)$$

where j is the radiance ($\text{Wm}^{-2} \text{sr}^{-1}$) and $\sigma = 5.669 \times 10^8 \text{ Wm}^{-2} \text{K}^{-4}$. For broadband measurements of j , inversion of Equation 2 could yield the LST.

Most surfaces are not perfect emitters, however, and a parameter called the emissivity (ε) is used to describe the efficiency with which they radiated heat. For a perfect emitter, $\varepsilon = 1$, but commonly $0.8 < \varepsilon < 1.0$. Therefore, for most surfaces $j = \varepsilon \sigma \pi^{-1} T^4$. Furthermore, ε varies with wavelength for many surfaces, including most geological surfaces of rock and soil (e.g., Lyon, 1965), so that Equation 1 also must be modified by including the multiplicative factor, $\varepsilon(\lambda)$. Inversion of this modified Planck function is generally used to calculate LST. Because it is underdetermined, however, additional information is required for solution. Providing these constraints is not straightforward, which is why there are numerous approaches. Figure 3 of “Land Surface Emissivity,” compares radiance, temperature, and emissivity data for a TIR image.

The discussion that follows addresses several factors that complicate the calculation of LST: effects of atmospheric absorption, emission, and scattering on the measured spectral radiance; effects of land surface heterogeneity, including skin effects, and spatial integration during measurement of spectral radiance; short-term temporal fluctuations in the temperature field; and simplifying assumptions and algorithms used to recover temperatures.

Atmospheric effects

The Earth’s atmosphere interacts with surface-emitted radiation as a function of surface elevation and atmospheric conditions, especially temperature and humidity profiles. Constituent gases such as ozone are also important. Atmospheric gases absorb differently across the spectrum, and at some wavelengths it is almost opaque. Remote sensing of the surface can only occur in atmospheric windows in spectral regions between these opaque bands. The three main windows for TIR remote

Land Surface Temperature, Figure 3 Radiance and transmissivity spectra. (a) Atmospheric transmissivity at sea level, zenith-nadir path (MODTRAN, mid-latitude summer atmosphere: Berk et al., 2005). (b) 300 K blackbody and sunlight reflected from a sea-level horizontal surface with 10 % albedo. Most remote-sensing detectors operate only within transparent atmospheric “windows” shown as labeled and shaded bars.

sensing are the longwave, mid-, and shortwave infrared (Figure 3). The maximum transmissivity $\tau(\lambda)$ of the atmosphere in the TIR is about 90 % (sea level). Therefore, it is necessary to account for atmospheric absorption and other effects quantitatively if accurate LSTs are to be recovered.

In addition to absorbing surface-emitted radiance, the atmosphere emits its own thermal energy in all directions. Two summary terms are important in the radiative transfer of energy from Earth to satellite: the upwelling “path radiance” ($L_{\uparrow}(\lambda)$) that never interacts with the land surface and the down-welling “sky irradiance” ($I_{\downarrow}(\lambda) = \pi L_{\downarrow}(\lambda)$), where $L_{\downarrow}$ is the equivalent average directional radiance (per steradian) term. Using these factors, the modified Planck function can be rewritten as

$$L(\lambda, T) = \tau(\lambda)\varepsilon(\lambda)B(\lambda, T) + L_{\uparrow}(\lambda) + \tau(1 - \varepsilon(\lambda))L_{\downarrow}(\lambda) \quad (3)$$

where L is the spectral radiance measured at the satellite and where the reflectivity and emissivity of the land surface are related by Kirchhoff’s law:

$$\rho(\lambda) = (1 - \varepsilon(\lambda)). \quad (4)$$

The atmospheric terms and τ , $L_{\uparrow}$, and $L_{\downarrow}$ are themselves functions of the angle of the exitant ray relative to local

zenith, as well as of the factors mentioned above. In evaluating Equation 3, it is important to note that there are five unknowns for a single spectral radiance measured from a homogeneous, isothermal surface. For multispectral data with n image channels at different wavelengths, there are $(1 + 4n)$ unknowns per measurement. This indeterminacy must be eliminated if LST is to be recovered.

Compensation for atmospheric effects

Before compensation can be attempted, the atmosphere must be characterized and the atmospheric parameters τ , $L_{\uparrow}$, and $L_{\downarrow}$ must be estimated. Probably the most common approach has been to use generalized atmospheric profiles of pressure, temperature, and humidity, from which the three parameters are estimated via an atmospheric radiative transfer model such as MODTRAN (e.g., Berk et al., 2005). Such an approach has been used in the retrieval of LST from Landsat TM5, for example, (Sobrino et al., 2004). This approach requires accounting for ground elevations using a digital elevation model (DEM).

It is potentially more accurate to estimate τ , $L_{\uparrow}$, and $L_{\downarrow}$ pixel by pixel, from the remote-sensing data themselves, as is done by MODIS to recover atmospheric profiles of temperature and humidity (Seaman et al., 2006). These profiles are then used in atmospheric radiative transfer models to calculate τ , $L_{\uparrow}$ and $L_{\downarrow}$. But profile recovery requires a complex sensor with many bands in and out of the LWIR window, and most remote-sensing platforms do not support this level of TIR measurement. Some airborne scanners such as NASA’s MODIS Airborne Simulator (MAS) do allow measurements across an H_2O absorption band at $0.93 \mu m$, from which total column water (TCW) can be estimated (Conel et al., 1988; Gao and Goetz, 1990). TCW can be used to constrain MODTRAN by scaling the default or assumed humidity profiles such that the measured integral is the TCW (Tonooka et al., 2005).

ASTER does not use internal image data to estimate atmospheric characteristics, but relies on reanalysis data from radiosonde balloons, launched routinely from weather stations and airports, interpolated to a 1° latitude/longitude grid and sampled every 6 h (e.g., Kalnay et al., 1996; Tonooka and Palluconi, 2005). They and a DEM are input to MODTRAN. The atmospheric data are available over the Internet (<http://www.cpc.ncep.noaa.gov/products/wesley/reanalysis.html>, last accessed 15 August 2008).

Because τ , $L_{\uparrow}$, and $L_{\downarrow}$ are partly correlated, it has proven possible to use just two LWIR channels in order to estimate them, provided the surface emissivities are known (Wan and Dozier, 1996). This is the case for the oceans, and such a two-channel or “split-window” algorithm for calculating sea surface temperature (SST) was developed and tested successfully early in the history of terrestrial remote sensing (Anding and Kauth, 1970). Details of this approach for SSTs are available in “Ocean, Measurements and Applications” and “Sea Surface Temperature.”

For images of constant or known high emissivity (~ 1.0), especially of grasslands or forests, it is possible to normalize the atmospheric τ and $L_{\uparrow}$ from channel to channel of a multispectral TIR image (Young et al., 2002), eliminating the need to measure it independently. In this approach, $L_{\downarrow}$ is overlooked because ρ is near zero. A reference channel ref is chosen, and variation diagrams are constructed in which $L(\lambda_i)$ is plotted against $L(\lambda_{ref})$ for enough pixels that a range of LSTs are represented. A line fit to the high radiance edge of the data cluster will have a slope of τ and an intercept of $L_{\downarrow}$, where these parameters are relative to those for the reference channel. This approach is successful in removing the appearance of atmospheric effects from multispectral images, but a whole-spectrum scaling still needs to be applied in order to accurately portray land-leaving spectral radiance.

Land surface heterogeneity

The temperature of the Earth's surface is variable in space and time at a wide range of scales. Both types of variability must be considered in TIR remote sensing.

Energy absorbed or radiated from the surface changes the "skin temperature" of the immediate surface. This establishes a temperature gradient into the surface, and the skin temperature is not a completely accurate representation of the temperature of even the upper few centimeters of the Earth. Sensible heat transport, for example, cooling by wind, also creates a temperature gradient. Because wind is rarely constant, the LST fluctuates on a scale of seconds or minutes, with an amplitude of a few Kelvin, especially over vegetation. The ephemeral variability of LST means that measurements by remote scanners, with a dwell time of milliseconds at each pixel, are hard to compare to other remote or in situ measurements, since the exact time of measurements are unlikely to be the same. This is sometimes called the "snapshot" problem.

These considerations are especially important for energy-balance studies and validation exercises for LST products. However, rapid temporal fluctuations are most severe at fine scales (e.g., 10^0 – 10^1 m) and are reduced at the moderate scales (e.g., 10^1 – 10^3 m) of many civilian TIR scanners such as MODIS or GOES.

LST variability from point to point also poses a problem, because the measured radiance is integrated from surface elements of different temperatures:

$$L(\lambda, T_e) = \int B(\lambda, T_{x,y}) dx dy. \quad (5)$$

where (x,y) are geographic coordinates. The temperature recovered by inversion of Equation 1 for the integrated spectral radiance yields an effective temperature, T_e . Because radiance is an exponential function of temperature, the exact relationship of T_e and the actual distribution of $T_{x,y}$ are hard to predict exactly and change over the day. For example, in a scene half covered by trees,

T_e in the morning will be weighted toward the temperature of the trees, which warm faster than rock, but in the evening T_e will be weighted toward the temperature of the rock surface, which cools more slowly. This may not be a serious concern to all analysts. As an example, for an afternoon scene with 50 % trees at 280 K and 50 % rocks at 310 K, the effective temperature will be 296.3 K, only 1.3 K greater than the average skin temperature. However, this error is noticeable in, for example, an ASTER image.

Directional effects

Many remotely sensed images are acquired looking straight down through the atmosphere, but wide-angle images from airborne scanners and from AVHRR and MODIS have off-nadir look angles as large as $\sim 55^\circ$. In addition to the dependency of atmospheric effects on the slant range, there are three effects that must be considered in calculating LST. These can lead to gradients in images of LST, such that the temperatures on the edges of the image may be hard to relate to those for equivalent surfaces viewed at nadir. First, in viewing rough surfaces at different angles, some views will include more shaded (typically cooler) surfaces, and others will include more sunlit surfaces (typically warmer). The magnitude of this effect depends on the time of day and the position of the sun, and the effect is minimized at night. However, during the day, the temperature difference between sunlit and shadowed surfaces may be 10 K or more, and the effect may be a few Kelvin across an LST image. This effect is not artifactual in that it is a faithful representation of the T_e field, and to remove it requires careful modeling and measurement of roughness. For daytime data, the ASTER stereo capability permits optical assessments of roughness (Mushkin and Gillespie, 2005) that could serve as input for such models. MODIS LST standard products have had to be made with the effects of non-Lambertian surfaces viewed at a range of angles from nadir in mind (Wan, 1999).

Second, specular reflection (Snyder and Wan, 1998) is also a factor at oblique view angles. This reflection is most obvious for smooth, mirrorlike surfaces such as lakes and ponds. The reflected emittance may be from the sky ($L_{\downarrow}$) or from neighboring landscape elements. For images acquired within $\sim 42^\circ$ of nadir, reflected radiance is generally minimal.

Third, the bidirectional reflectance distribution (BRDF) of the surface may not be isotropic (e.g., Wan and Dozier, 1992). According to Kirchhoff's law, this means that a surface will look hotter from some angles than others. For rough surfaces, temperature differences due to shadowing (see above) can masquerade as an anisotropic BRDF; other surfaces may inherently be anisotropic. Because it is necessary to characterize the surface before the BRDF can be compensated for, it has been necessary to use generalized approaches (e.g., Wan, 1999).

Algorithms for calculating LST

Consideration of all the fluxes and factors contributing to the spatially integrated measurement of spectral radiance shows that accurate LST estimation is only possible under restricted circumstances or with independent constraints and simplifying assumptions. For example, it may be necessary to regard the landscape pixel as having a known, single emissivity ε and an effective temperature T_e which may, in fact, exist nowhere within the pixel. However, over decades of study, the assumptions have proven reasonable, and T_e has proven to be a useful measure.

Below, several common approaches for recovery of T_e are discussed. They are based either on the amplitude of the spectral radiance or on the shape of the spectrum if two or more image channels are measured. All approaches here are described assuming that the spectral range of measurement, $\Delta\lambda = f_2 - f_1$, is very narrow. If this is not the case, a calibration must be done to estimate the spectral radiance at the central wavelength of the sensor response $f(\lambda)$:

$$L(\lambda, T) \approx \frac{\int_{\lambda=f_1}^{f_2} f(\lambda)\varepsilon(\lambda)B(\lambda, T)d\lambda}{\int_{\lambda=f_1}^{f_2} f(\lambda)d\lambda} \quad (6)$$

Brightness temperature, T_b

The simplest estimate of LST is T_b , the temperature at which a blackbody ($\varepsilon \equiv 1.0$) would emit the remotely measured radiance. This approach is used when there is a single image channel. Finding T_b requires inverting the Planck function:

$$T_b = \frac{c_2}{\lambda \ln\left(\frac{c_1}{B(\lambda, T)\pi\lambda^5} + 1\right)} \quad (7)$$

where it is understood that λ refers to the central wavelength of the image channel.

Model temperature, T_m

In a slight variation, the surface emissivity may be estimated a priori to provide a refined estimate of LST (T_m). If the surface composition is known, the emissivity may be found from one of several spectral libraries available online (e.g., <http://speclib.jpl.nasa.gov>, last accessed 15 August 2008). For water and closed-canopy vegetation, the LWIR emissivity is >0.98 . Many soils also have a high emissivity, >0.95 . Lyon (1965) pointed out that, for most rocks, the emissivity at $\sim 10 \mu\text{m}$ is ~ 0.95 .

Once ε has been estimated, LST is found by

$$T_m = \frac{c_2}{\lambda \ln\left(\frac{c_1}{\varepsilon(\lambda)B(\lambda, T)\pi\lambda^5} + 1\right)} \quad (8)$$

Image classification has been used to determine surface composition, from which ε can be inferred. For example, van de Griend and Owe, (1993) showed that in the 8 – 14 μm spectral range, ε is highly correlated with NDVI, the normalized difference vegetation index, for different vegetation types:

$$\varepsilon \approx a + b \ln NDVI; NDVI = \frac{\rho_{0.85} - \rho_{0.65}}{\rho_{0.85} + \rho_{0.65}} \quad (9)$$

where ρ is evaluated at near-infrared ($\lambda = 0.85 \mu\text{m}$) and visible red ($\lambda = 0.65 \mu\text{m}$) wavelengths. Equation 9 allows ε to be estimated pixel by pixel, improving LST estimates especially for agricultural areas with simple geological substrates (homogeneous soils). Empirical coefficients a and b in Equation 9 are dependent on substrate emissivities, but if these can be estimated it is possible to extend greatly the range of surfaces for which accurate model LSTs can be calculated.

Model temperatures have been calculated for lava flowing from volcanoes, using Landsat Thematic Mapper (TM) Band 7 (2.25 μm) images and emissivities appropriate for lava (Pieri et al., 1990). The SWIR bands are effective because the peak thermal radiance is near 2 μm , whereas the emitted TIR radiance is too high and exceeds the dynamic range of the TIR band. Care must be taken because the emissivity of the hot lava appears to vary with temperature (Abtahi et al., 2001).

Color temperature, T_c

The simplest approach that utilizes the changing shape of the Planck function to estimate LST is a ratio of two spectral bands centered at λ_a and λ_b , and for which emissivities are known. The ratio is a monotonic function of temperature:

$$\frac{L(\lambda_a, T)}{L(\lambda_b, T)} = \frac{\varepsilon(\lambda_a)\lambda_b^5}{\varepsilon(\lambda_b)\lambda_a^5} \left(\frac{\exp\left(c_2(\lambda_b T)^{-1}\right) - 1}{\exp\left(c_2(\lambda_a T)^{-1}\right) - 1} \right). \quad (10)$$

Generally, it is assumed that $\varepsilon(\lambda_a) = \varepsilon(\lambda_b)$. Equation 10 is sometimes simplified further (Wien's approximation) by ignoring the (-1) term, such that

$$T_c = \left(\frac{c_2}{\lambda_b} - \frac{c_2}{\lambda_a} \right) \left(\ln \left(\frac{L(\lambda_a, T)\lambda_a^5}{L(\lambda_b, T)\lambda_b^5} \right) \right)^{-1} \quad (11)$$

For typical LSTs (e.g., 300 K), T_c is best calculated for widely separated central wavelengths, for example, 3 and 10 μm , because the ratio is more sensitive to LST, and therefore measurement precision has less of an effect on the recovered T_c . However, the use of MIR channels is generally limited to night time data because of the need to make large corrections for reflected sunlight.

Generalized split-window algorithm

Wan and Dozier, (1996) showed that provided the emissivity was known, the SST algorithm could be generalized for use over land. This algorithm is based on spectral radiance differences rather than ratios and has empirical coefficients a and b that permit the elimination of atmospheric effects. The form is

$$T_s = T_4 + \frac{1}{a-1}(T_4 - T_5) - \frac{b}{a-1} \quad (12)$$

T_4 and T_5 are the brightness temperatures for AVHRR (Advanced Very High Resolution Radiometer) bands 4 and 5 (10.8 and 11.9 μm) or MODIS bands 31 and 32. Equation 12 can be generalized further to account for directional effects, but is still of the form of a difference equation.

Summary and conclusions

Temperature and emissivity are generally both unknown for “geological” surfaces of rock and soil and must be solved for simultaneously using inversion of Planck’s equation. These algorithms thus go beyond just finding LST and are discussed in the entry “Land Surface Emissivity.”

Because of the underdetermined nature of the modified Planck equation (Equation 2), no single solution for LST has been found that satisfies all analysts. Therefore, literally dozens of algorithms have been proposed, tested, and applied. This entry summarized only a few, representative of the basic approaches.

Definition

Topography of the Land Surface. The three-dimensional arrangement of physical attributes (such as shape, height, and depth) of a land surface in a place or region. Physical features that make up the topography of an area include mountains, valleys, plains, and bodies of water. Human-made features such as roads, railroads, and landfills are also often considered part of a region's topography (American Heritage Science Dictionary, 2005).

Importance of topographic information

The topography of the land surface is one of the most fundamental geophysical measurements of the Earth, and it is a dominant controlling factor in virtually all physical processes that occur on the land surface. Topography of the land surface also significantly controls processes within the overlying atmosphere, and it reflects the processes within the underlying lithosphere. Consequently, topographic information is important across the full spectrum of earth sciences.

Precipitation, runoff, soil moisture, incident sunlight, and temperature all vary with topography. Consequently, topography dominantly controls the local and regional distribution and character of vegetation. Erosion and sedimentation, and consequently soil formation and nutrient transport, also are strongly controlled by topography and are key factors in ecological studies. Topography strongly influences the location and magnitude of surface and subsurface water flow. Modeling of water supply and flood potential requires knowledge of the area's drainage extent, its slopes, and the pattern of the drainage network.

Particularly in rugged terrain, topography is commonly the dominant variable in remote sensing imagery. Topographic shading affects the radiance measured at every wavelength and is consequently the statistical principal component of many remotely sensed data sets. Meanwhile, atmospheric optical thickness varies inversely with topographic height, so that topography is an important factor in the atmospheric correction of remotely sensed data. Topographic data are imperative for the orthorectification of satellite imagery.

While topography controls many natural processes at and near the Earth's surface, many natural processes conversely control topography. Consequently, to various

degrees, topography records and reveals evidence of current and past natural processes. An obvious example is the development and occurrence of erosional and depositional fluvial landforms. Tectonic, volcanic, glacial, and gravitational processes also produce characteristic landforms that reveal past and ongoing change. Consequently, topographic information is an important tool in the study of such processes (Crippen, 2008).

Describing the topography of the land surface

A *topographic map* (Figure 1) is a planimetric, or two-dimensional, representation of the three-dimensional configuration of the land surface where relief, or change in elevation, typically is represented by *contour lines*. A contour line is a line traced on the map such that all points on that line have the same elevation. That is, contour lines describe continuous points of equal elevation.

Until recent years, paper topographic maps were the most common tool used to describe the topography of the land surface. Until about 1940, most topographic maps were made by field crews who used alidades and plane tables to survey and map the topography of the landscape. World War II ushered in the age of *aerial photogrammetry* as the most common method for making topographic maps. This method, which uses overlapping and nadir-looking aerial photographs and a stereoplotter, revolutionized topographic mapping, resulting in greatly increased map coverage and enhanced map standardization (USGS, 1998).

Advances in computer technology brought about the latest great change in topographic mapping, the digital mapping revolution. Perhaps most notable was the replacement of the analog stereoplotter by the computer-assisted analytical stereoplotter. Not only has computer-assisted map production made it easier to make new paper maps and revise old ones, computer technology has accelerated demand for topographic data and other map information in *digital form* for use with the ever-growing number of computer-based mapping applications (McGlone, 2007).

A digital elevation model or DEM (Figure 2) is the generic term used most frequently to denote digital topographic data in all their various forms. The word "model" is applied because computers can use such data to model and automatically analyze the Earth's topography in three dimensions, thus avoiding much time-consuming human interpretation (Maune et al., 2007). Digital terrain model (DTM) and digital surface model (DSM) are two other common terms with similar meaning to DEM.

A *DEM* is a digital file consisting of terrain elevations for ground positions at regularly spaced horizontal intervals. The shorter those intervals are, the higher the spatial resolution of the DEM. The U.S. Geological Survey National Elevation Dataset (NED) typically has elevation data spaced at 30 m intervals, and it is thus said to have 30 m postings. DEMs are referenced to a vertical

Land Surface Topography, Figure 1 Part of USGS 1:250,000 topographic map of the Drum Mts., Utah, area.

datum, such as the WGS84/EGM96 geoid, and to a geographic coordinate system, such as Universal Transverse Mercator (UTM).

Determining land surface topography from remotely sensed digital data

Many DEMs have been, and continue to be, generated by digitizing topographic maps produced largely by aerial photogrammetric techniques. However, today most DEMs of the Earth's land surface are being generated, using a variety of automated processes, directly from digital data acquired by a rather large variety of airborne sensors and land surface-imaging satellite systems.

Most DEMs produced today from remotely sensed digital data are derived from one of three primary sources: optical imaging systems, interferometric synthetic aperture radar systems, and lidar systems (McGlone, 2007).

Optical imaging systems

Three types of optical imaging sensors are used for photogrammetric production of DEMs: airborne film cameras, airborne digital sensors, and digital sensors onboard satellites. *Film mapping cameras*, for decades the staple of aerial photogrammetric mapping, continue to be important sources of stereo images for DEM generation. Aerial film is scanned by high-resolution scanners to produce digital

Land Surface Topography, Figure 2 DEM intensity image (*left*) and DEM shaded relief image (*right*) of the Drum Mts., Utah.

images that can be processed by a softcopy stereoplotter or by one of the many available DEM generation software systems (McGlone, 2007).

Airborne and spaceborne digital sensors capable of collecting imagery useful in the generation of DEMs have certain similarities, but they also have important differences. Airborne systems are essentially digital mapping cameras capable of acquiring very high-spatial-resolution images, but typically with fewer spectral bands than spaceborne optical imaging systems. Stereo acquisition by airborne digital sensors typically is achieved by overlap of successive images acquired along the flight path of the aircraft, similar to film mapping cameras.

Optimal stereo coverage for DEM generation by satellite sensors is achieved along the orbital track of the satellite by using two (or more) sensors. One of the sensors is nadir looking, while the other points at some fixed angle along the orbital track fore and/or aft of the spacecraft. Some satellite systems acquire stereo imagery from adjacent orbits by pointing across track, and some are able to acquire limited stereo coverage along the same orbit using a single sensor that looks forward to image an area from one angle and then is pointed backward to image the same area from a different angle.

Generating DEMs from imagery acquired by airborne or spaceborne digital sensors is accomplished with the aid of a softcopy stereoplotter or one of the many available DEM generation software systems. The process may or may not employ the use of ground control points (GCPs), and it typically involves a sequence of steps that include selecting tie points in each of the stereo pair, co-registration of the stereo images, stereo correlation for parallax difference measurement (image matching), and calculation of elevation values. In the co-registered stereo

images, any positional differences between common points parallel to the direction of travel (parallax differences) are attributed to displacements caused by relief. Relative ground elevations are determined by measuring the parallax differences in the registered images, which then are converted to elevation (Lang and Welch, 1999).

Interferometric SAR systems

Synthetic aperture radars (SAR) illuminate the Earth's surface with microwave pulses, and they receive and record the return signals with respect to the magnitude and phase of those sine wave pulses (Bamler, 1997). While it is possible to generate accurate DEMs from stereo radar images using techniques similar to those described for optical imaging systems, DEMs are generated more commonly from *interferometric synthetic aperture radar* (InSAR).

InSAR exploits the phase of SAR signals to measure stereo parallaxes to an accuracy of a fraction of a wavelength. The phase of the return radar wave depends on the distance to the ground, so it is possible to accurately determine land surface elevation on a pixel-by-pixel basis from the phase information. To generate a DEM, InSAR uses two SAR images of the same land surface area taken from slightly different positions and determines phase differences between them, producing an image called an *interferogram*. Further processing of the interferogram results in the generation of a DEM of the land surface imaged by the two sensors (Hensley et al., 2007).

Lidar systems

Lidar stands for Light Detection and Ranging, and like radar, it is an active remote sensing system. Lidars use

laser technology to measure distances to specific points by transmitting pulses or continuous waves of light, amplifying the light that is scattered back, and recording the precise time the transmitted pulse takes to travel to the target and back (Fowler et al., 2007). Most lidar systems used today to produce DEMs are airborne systems, and they employ a variety of different beam steering or scanning strategies. They also operate at a wide range of altitudes above the land surface, depending on the resolution requirements for the DEM to be produced. DEMs produced from lidar data typically have significantly greater spatial detail and better accuracy than DEMs produced from optical imaging systems or InSAR.

Lidar is a complex remote sensing technology, and the data processing required to convert raw lidar data to DEMs also is complex. Typically, such processing is done by the company or agency that collects that data, because the processing software has been developed specifically for the lidar system that collected the data (Fowler et al., 2007). The lidar product most commonly associated with topography is a DEM known as the *bare earth model*,

Land Surface Topography, Figure 3 Example of bare earth model DEM produced from lidar data collected over North Carolina.

which is a product from which the processing has removed virtually all returns not associated with the bare land surface (Figure 3).

Satellite systems that produce topographic data

This section briefly examines the system and data characteristics of selected Earth-observing *satellite systems* that acquire or have acquired data from which DEMs of the global land surface can be or have been generated. Airborne systems provide data from which highly accurate DEMs can be produced, but there is not one program or system that can provide such data for anywhere on the Earth's surface. The international remote sensing and earth science communities need access to quality DEMs for the entire global land surface, hence the emphasis here on satellite systems.

Radar satellite systems

Beginning in 1991, a number of polar-orbiting SAR satellite systems have been in operation, providing a continuous collective capability to acquire InSAR data from which DEMs can be generated for virtually any place on the global land surface. However, it was not until the 2010 launch of TanDEM-X, which operates in tandem formation with TerraSAR-X, that systematic efforts to produce a consistent global DEM from InSAR data were undertaken. Table 1 lists the SAR satellite systems that have contributed to DEM generation over the past two decades.

Shuttle radar topography mission (SRTM)

In 2000, the US National Aeronautics and Space Administration (NASA) and National Geospatial-Intelligence Agency (NGA) cooperated with the German Space Agency (DLR) to fly a Space Shuttle mission dedicated to acquiring digital topographic data for more than 80 % of the Earth's land surface. NASA flew a C-band SAR and DLR flew an X-band SAR, both of which were configured with one antenna in the bay of the space shuttle and the other at the end of a 60 m collapsible mast. The mission lasted 11 days, and NASA's C-band SAR collected complete InSAR coverage of the global landmass between 60 °N to 56 °S latitude. The X-band SAR was not designed for uninterrupted coverage.

Land Surface Topography, Table 1 International SAR systems from which DEMs can be produced from InSAR data

Country/agency	Satellite/sensor	Band	Launch date	Still active
European Space Agency (ESA)	ERS-1	C-band	1991	No
ESA	ERS-2	C-band	1995	No
Canadian Space Agency (CSA)	RADARSAT-1	C-band	1995	No
CSA	RADARSAT-2	C-band	2007	Yes
Japan (JAXA)	JERS-1	L-band	1992	No
ESA	Envisat ASAR	C-band	2002	No
Japan (JAXA)	ALOS PALSAR	L-band	2006	No
Germany (DLR)	TerraSAR-X	X-band	2007	Yes
Germany (DLR)	TanDEM-X	X-band	2010	Yes

The SRTM DEM data set is available from NASA and from the U.S. Geological Survey at no charge to users. Data are at 1 arc-second (30 m) for the United States and its territories and 3 arc-seconds (90 m) for all other covered areas. Vertical accuracy specification for the 1 arc-second data was 16 m (Rabus et al., 2003), but the data frequently have vertical accuracies better than 10 m (at 90 % confidence).

SPOT satellites

The French Système Pour l'Observation de la Terre (SPOT) satellites have been capable of acquiring cross-track stereo digital imagery from which DEMs can be generated since their initial launch in 1984. Spatial resolution of SPOT sensors has increased over that time, so the spatial details of DEMs that can be generated from those data likewise have increased. Currently, SPOT Image offers for sale DEMs produced from SPOT optical image data that cover most of the global land surface. The DEMs have 30 m postings and a vertical accuracy of less than 10 m where the slope of terrain is less than 20 %.

ASTER

The Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) was built by the Japanese Ministry of Economy, Trade and Industry (METI), and it flies onboard NASA's Terra satellite. ASTER collects along-track stereo optical data with 15 m spatial resolution from which DEMs with 30 m postings are routinely produced as standard data products without the need for GCPs. The accuracy of ASTER DEMs varies some depending on terrain and other conditions, but they routinely have vertical accuracies better than 15 m (Fujisada et al., 2005). ASTER 60 km by 60 km DEMs are available for purchase to the general user from METI's Earth Resources Data Analysis Center and NASA's Land Processes Distributed Active Archive Center.

Since ASTER was launched in late 1999, more than two million scenes have been acquired of the global land surface. NASA and METI cooperated to produce a global DEM from these ASTER data. The *ASTER Global DEM*, which covers the Earth's landmasses from 83 °N to 83 °S latitude with nominal accuracies of 20 m vertical and 30 m horizontal at 95 % confidence, has 30 m postings. The ASTER Global DEM was contributed to the Global Earth Observing System of Systems (GEOSS) by NASA and METI, and thus it is available at no cost to users worldwide.

Cartosat and prism

Two optical imaging satellite systems that were designed to acquire data for generation of DEMs are the Indian Space Research Organisation's (ISRO) Cartosats and the Japanese Aerospace Exploration Agency's (JAXA) Prism sensor that flew onboard the Advanced Land Observation Satellite (ALOS). All acquire stereo image data along the orbital track. Cartosat-1 has a spatial resolution of 2.5 m

with a 30 km swath, and Cartosat-2 has a spatial resolution of less than 1 m with a 9.6 km swath. Prism has a 2.5 m spatial resolution and a 35 km swath. DEMs are not offered as standard products by either ISRO or JAXA, but the image data are available for purchase.

Summary and conclusions

The topography of the land surface is one of the most fundamental geophysical measurements of the Earth, and it is a dominant controlling factor in virtually all natural physical processes that occur on the land surface. The topographic map, which is a planimetric representation of the three-dimensional land, has been the most common tool used to describe the topography of the land surface until recently. Now, digital topographic data, in the form of a DEMs, are the tools of choice for many who wish to characterize the topography of the land surface.

DEMs are most frequently generated by automated computer techniques from digital data acquired by airborne and spaceborne sensors. Locally to regionally, airborne film and electro-optical systems and lidar systems provide users with high-quality and very accurate DEMs. For global studies, spaceborne optical systems capable of acquiring stereo imagery and InSAR systems offer the opportunity to produce DEMs with improving quality and accuracy worldwide. The SRTM DEM that cover 80 % of the global land surface and the ASTER Global DEM that covers virtually all of it are examples of two recent contributions by land remote sensing systems to better characterize the global land surface topography. Almost certainly, even greater advancements will be achieved in the next few years.

Evaporation; Water flux

Definition

Evapotranspiration (ET). The transfer of liquid water from open water and through plant transpiration to the atmosphere as water vapor.

Transpiration. The loss of water vapor through plant pores called stomata on leaves/needles or stems.

Basics of evapotranspiration

Evapotranspiration (ET) is the movement and transfer (i.e., flux) of water as a liquid at the Earth's surface to the atmosphere as a gas. ET is a combination of open water evaporation and plant transpiration. (Sublimation, which is the transition of solid water (i.e., ice, snow) to vapor due to low atmospheric pressure (i.e., high altitude), dry air, and high sunlight, is generally considered separate from ET.) Sources of open water evaporation could include oceans, seas, lakes, rivers, ponds, puddles, and water on objects such as plants, buildings, rocks, the soil surface (including movement of water vertically through the soil to the surface), or in the context of measuring devices such as a pan. Plants take up water from the soil through their roots, transferring that water through

their stems via conduits called xylem to their leaves, where it is used in the process of photosynthesis. The photosynthetic machinery in leaves (e.g., chlorophyll) takes in CO₂ from the atmosphere through stomatal pores and combines it with water and energy (i.e., light) to create sugars used to maintain and grow plant tissue and functions. While stomata are open, plants may lose water from their leaves to the atmosphere – this water loss is called transpiration. Plants regulate the opening and closing of their stomata to minimize water loss (closed), yet maximize CO₂ absorption (open).

Energy is required to break the strong bonds that hold water molecules together as a liquid – when those bonds break, the individual water molecules may enter the surrounding atmosphere as vapor. Energy may be in the form of heat, radiation, or pressure. Regardless of the availability of energy, water molecules may not be able to enter the atmosphere if the atmosphere is already saturated with moisture (humidity) or if there is no wind to facilitate the transfer of the molecules from the water source to the atmosphere. The wind itself may be differentially influenced by friction as it passes over smooth versus rough surfaces. Therefore, solar radiation (or, indirectly, air temperature), air humidity, and wind speed are the main climate influences on ET. The main vegetative controls include leaf and canopy structures, regulation of stomata, and rooting dynamics. Finally, soil characteristics control soil moisture retention of precipitation inputs. All of these potential controls vary in influence depending on the system in question, as well as the associated spatial and temporal scales of analysis (Fisher et al., 2011).

Remote sensing of ET

ET can be measured “remotely” with instruments attached to towers extending over vegetation using the eddy covariance technique (e.g., FLUXNET: Baldocchi et al., 2001). These same instruments may be attached to airplanes for regional measurements. However, ET cannot be measured directly from satellite remote sensing, so it must be inferred from a model or the residual of other measurements. There are three orders of complexity in space-based estimation of ET:

- Simple: Empirical, semiempirical
- Intermediate: Water balance, energy balance
- Complex: Land surface/Earth system models

Empirical, semiempirical approaches

One of the simplest approaches to estimating ET is to take another closely related variable that is measureable and convert that to ET using a statistical relationship. The statistical relationship (e.g., linear regression) may be developed from studies where both the other variable and ET were measured and then used to extrapolate beyond the site. One commonly used variable is the Normalized Difference Vegetation Index (NDVI), as well as related “greenness” indices, constructed from

measurements primarily in the red and near-infrared (NIR) wavelengths, and which is indicative of plant productivity. Where there is plenty of water and energy, there will be both high NDVI and ET; where there is no water and energy, one would not expect much NDVI and ET. However, this relationship may fall apart, for example, under deforestation or nutrient limitation (high ET, low NDVI), or diurnal/seasonal water stress (low ET, high NDVI). NDVI may be obtained from satellite instruments such as the Advanced Very High Resolution Radiometer (AVHRR), the Moderate resolution Imaging Spectroradiometer (MODIS), or the Visible Infrared Imager Radiometer Suite (VIIRS).

Another commonly used variable is Land Surface Temperature (LST), constructed from thermal-infrared (TIR) measurements. A given surface may be cooled (lower LST) when evaporating and hotter when there is less ET. However, other forces may change the temperature of the surface, including advecting warm/cool/dry/moist air. LST may be obtained from satellite instruments such as MODIS, the Atmospheric Infrared Sounder (AIRS), or Landsat. LST may be combined with NDVI for a somewhat more complex empirical approach. One of the leading empirical approaches comes from the MPI-BGC product, which is constructed from a machine learning technique and model tree ensemble that developed statistical relationships between measured ET and globally available ancillary data at over 250 FLUXNET sites (Jung et al., 2009). Finally, many agriculturalists use semiempirical algorithms to estimate ET, using physics-based equations for potential ET (PET), then converting or downscaling PET to actual ET (AET) using an empirical scalar multiplier, called a crop coefficient, developed for their specific crop and location.

Water balance

ET may be calculated as the residual of known measurements in the water balance equation:

$$P = dS + Q + ET \quad (1)$$

where P is precipitation (rainfall and snow); dS is the change in stored standing water (e.g., lakes, ponds, or in/on plants), soil moisture, and groundwater; and Q is runoff. From a remote sensing standpoint, rainfall is measured from a variety of satellites including the Tropical Rainfall Measuring Mission (TRMM) (the Global Precipitation Mission (GPM) is currently in development as the next major multi-satellite precipitation-measuring mission) and snow from MODIS. dS is measureable at large spatial scales from the Gravity Recovery And Climate Experiment (GRACE). Q is not yet measureable from space, (The proposed Surface Water Ocean Topography (SWOT) mission currently in development would measure river discharge from space.) but is readily obtained from river discharge measurements, though many rivers are sparsely instrumented, for

example, in developing nations. Equation 1 may be rearranged to solve for ET given the known measurements of the three other variables in the equation.

Energy balance

ET may also be considered an energy (water fluxes such as precipitation and ET are usually given in units of depth per time (i.e., $\text{mm} \cdot \text{day}^{-1}$); the units are consistent when they are in volume per area per time (i.e., $\text{m}^3 \cdot \text{ha}^{-1} \cdot \text{day}^{-1}$). 1 m^3 is equal to 1,000 l. Water can also be expressed in units of mass – 1 kg of water is equal to 1 mm of water spread over 1 m^2 . ET , like R_n , can be expressed in units of energy too. Because it requires 2.45 MJ to vaporize 1 kg of water (at 20°C), 1 kg of water is therefore equivalent to 2.45 MJ; 1 mm of water is thus equal to $2.45 \text{ MJ} \cdot \text{m}^{-2}$) variable, called the latent heat of evaporation (LE), as it requires a certain amount of energy to convert a given quantity of liquid water to gas. Energy coming from the sun less any radiation that gets reflected back to the atmosphere – or net radiation (R_n) – is energy available to drive ET. Any R_n that does not drive ET either gets converted to sensible heat (H) or stored in the soil or other objects (G):

$$R_n = ET + H + G \quad (2)$$

A few space-based R_n are available, including those from the Surface Radiation Budget (SRB), the Clouds and Earth's Radiant Energy System (CERES), the International Satellite Cloud Climatology Project (ISCCP), and MODIS. H and, to a lesser extent, G are not remotely measureable and are the focus of models such as the Surface Energy Balance System (SEBS), the Atmosphere-Land Exchange Inverse (ALEXI), the Surface Energy Balance Algorithm for Land (SEBAL), and Mapping EvapoTranspiration at high Resolution with Internalized Calibration (METRIC), all of which rely particularly on remotely sensed LST (Li et al., 2009).

Direct approaches

ET may also be calculated “directly” from the physics that control ET, as outlined earlier in the “Basics of Evapotranspiration” subsection. The most widely used equation for determining ET comes in the form of the Penman-Monteith equation:

$$ET = \frac{\Delta R_n + \frac{c_p \rho VPD}{r_a}}{\Delta + \gamma + \gamma \left(\frac{r_s}{r_a} \right)} \quad (3)$$

where Δ is the slope of the saturation-to-vapor pressure curve, c_p is the specific heat of water, ρ is air density, VPD is vapor pressure deficit, r_a is aerodynamic resistance, γ is the psychrometric constant, and r_s is surface resistance. Equation 3 forms the foundation of the algorithm for the official MODIS ET product (MOD16) (Mu et al., 2011), which relies on MODIS-based leaf area index (LAI), fraction of absorbed photosynthetically active radiation (fAPAR), land cover, and a general

Land-Atmosphere Interactions, Evapotranspiration, Figure 1 Mean monthly ET for 2004 from the PT-JPL product.

biome-specific lookup table to parameterize the resistances. R_n , VPD , and air temperature (T_a ; i.e., included in Δ) in MOD16 are derived from the NASA/GMAO Modern Era Retrospective Analysis (MERRA).

The PT-JPL product (Figure 1: Fisher et al., 2008) is based on the PET formulation of the Priestley-Taylor equation, which is a reduced version of the Penman-Monteith equation, eliminating the need to parameterize the stomatal and aerodynamic resistances, leaving only equilibrium evaporation multiplied by a constant (1.26) called the α coefficient:

$$PET = \alpha \frac{\Delta}{\Delta + \gamma} R_n \quad (4)$$

PET is reduced to AET using ecophysiological constraint functions (f -functions, unitless multipliers, 0–1) based on atmospheric moisture (VPD and relative humidity, RH) and vegetation indices ($NDVI$ and $SAVI$):

$$ET = ET_s + ET_c + ET_i \quad (5)$$

$$ET_c = (1 - f_{wet}) f_g f_T f_M \alpha \frac{\Delta}{\Delta + \gamma} R_{nc} \quad (6)$$

$$ET_s = (f_{wet} + f_{SM})(1 - f_{wet}) \alpha \frac{\Delta}{\Delta + \gamma} (R_{nc} - G) \quad (7)$$

$$ET_i = f_{wet} \alpha \frac{\Delta}{\Delta + \gamma} R_{nc} \quad (8)$$

where ET_s , ET_c , and ET_i are evaporation from the soil, canopy, and intercepted water, respectively, each calculated explicitly. f_{wet} is relative surface wetness (RH^4), f_g is green canopy fraction (f_{APAR}/f_{IPAR}),

f_T is a plant temperature constraint ($\exp(-((T_{max} - T_{opt})/T_{opt})^2)$), f_M is a plant moisture constraint ($f_{APAR}/f_{APARmax}$) and f_{SM} is a soil moisture constraint, (RH^{VPD}). f_{APAR} is absorbed photosynthetically active radiation (PAR), f_{IPAR} is intercepted PAR, T_{max} is maximum air temperature, T_{opt} is T_{max} at $\max(R_n T_{max} SAVI/VPD)$, and G is the soil heat flux.

Land surface models/Earth system models

The most complex approach to estimating ET is through full Land Surface Models (LSMs) or Earth System Models (ESMs). These models are typically driven by meteorological data and aim to simulate all of the relevant biogeochemical processes and states governing the exchange of energy, water, and carbon throughout the entire land surface or complete Earth system, including ocean and atmosphere. Some of these models assimilate any relevant observation from both space and in situ to constrain the complexity of linkages and feedbacks. While the estimate of ET from LSMs and ESMs is subject to potentially greater uncertainty relative to the previously described approaches due to increased complexity and degrees of freedom, LSMs and ESMs allow more realistic feedbacks to and from ET given changes in the Earth system or climate (Mueller et al., 2011).

Summary

Remote sensing of ET is currently a high-level research and science priority, especially as ET is central to connecting the water, energy, and carbon cycles; a modulator of regional rainfall; a significant factor in flood and drought processes and models; the primary climatic predictor of biodiversity; and critical for the agricultural industry. In situ measurement of ET requires

cost-constraining equipment; as such, major international efforts, such as the Global Energy and Water Cycle Experiment (GEWEX), have focused on determination of ET from existing remote sensing assets (Jiménez et al., 2011; Vinukollu et al., 2011). The techniques described here provide an overview of how the scientific community estimates ET from remote sensing.

Debris flow; Mass movement; Mudslide; Rock avalanche

Definition

Landslide is used to describe the downslope movement of soil and rock under the effects of gravity. In some cases, other terms such as mass movements and slope failure are used interchangeably with landslides. The most common triggers of landslides are earthquakes, heavy rains, thawing of frozen ground, river and coastal erosion, and frequent infrastructure and building development. Many types of landslides are usually associated with specific mechanics of slope failure and the properties and characteristics of failure type. Figure 1 shows a simple illustration of a rotational landslide which illustrates the commonly used labels for the parts of a landslide.

Introduction

Landslides are among one of the serious geological hazards which threaten and influence the socioeconomic conditions of many countries (Schuster, 1996). They are the manifestation of slope instability. An example of their destructive nature is shown in Figure 2. The La Conchita landslide in California killed ten persons. Geologists and engineers have long tried to identify the conditions of slope failure and mitigate their risk to infrastructure and populated areas.

There are various techniques used to map and evaluate landslides. Large-scale, stereo aerial photographs are one of these tools that have been extensively used in landslide investigations. Because of their three-dimensional capability, they provide essential geologic and geomorphic information necessary for landslide inventory mapping. Recently, there has been increasing uses of high-resolution satellite images (1–5 m) for various landslide investigations. The recent advances in radar interferometry are providing valuable insights in monitoring slow-moving landslides. The following section briefly discusses the uses of these techniques in landslide investigations.

Landslide mapping

Stereo aerial photographs are used extensively to produce landslide inventory maps. They allow the identification of geomorphic, geologic, and related land use features related to landslides (Mollard and Janes, 1993). Geological and geomorphologic units related to landslide inventories can be interpreted on the basis of morphological, textural, and structural characteristics using stereo aerial photos and high-resolution satellite images. Landslide inventory maps are usually published at various scales, such as national (1; 1,000,000), regional (1:100,000), medium (1:25,000–50,000), and large scales (>1:15,000).

For instance, detail inventory requires detail aerial photos and high-resolution satellite images to assist the interpreter to make conclusions on types and causes of the landslide. Recently, the high-resolution satellite Google images provided a cheap and valuable source of

Landslides, Figure 1 Parts of a landslide (Modified from Varnes (1978), by Highland and Bobrowsky (2008)).

Landslides, Figure 2 This landslide occurred at La Conchita, California, USA, in 2005. Ten people were killed (USGS Photo).

locating landslides before and after the devastating earthquake in Haiti in January 2010 (Figure 3).

Other high-resolution optical systems (1–5 m) such as IKONOS, Quickbird, and IRS images and the stereo capability of SPOT 5 are useful for landslide recognition

and related land use mapping. Whenever possible, the highest-resolution images should be used to identify and interpret the geomorphic and associated features shown in Figure 1. Large landslides are easily recognized from medium resolution 30 m Landsat TM images.

Landslides, Figure 3 Landslides near Port-au-Prince, before and after Haiti earthquake.

Recent research has shown that high-resolution stereo radar and optical images, combined with topographic and geological information, have assisted in mapping the geomorphic characteristics of deep-seated landslides needed to produce of landslide inventory maps (Singhroy et al., 1998; Singhroy, 2005). The multi-incidence angle, stereo, and high-resolution capabilities of the various radar satellites are particularly useful in providing terrain and geomorphic information needed to produce landslide inventory maps.

Currently, damage assessment related to landslides and other disasters in support of relief efforts uses aerial photography, videos, high-resolution satellite images, and ground checks.

Landslide monitoring using InSAR

Landslides usually resulted in extreme economic and societal costs, despite our increased understanding of the mechanisms of failure and large ground deformation. Current state of the art in real-time monitoring of active slopes developed for early warning of landslides is very expensive. Satellite radar interferometry is used increasingly to complement real-time monitoring such as GPS and in situ field measurements (Singhroy, 2008).

Interferometric Synthetic Aperture Radar (InSAR) techniques are being used to measure small millimeter displacement on slow-moving landslides. An interferometric image represents the phase differences between the backscatter signals in two SAR images obtained from similar positions in space. In case of spaceborne SAR, the images are acquired

from repeat-pass orbits. The phase differences between two repeat-pass images result from topography and from changes in the line-of-sight distance (range) to the radar due to displacement of the surface or change in the atmospheric propagation path length. For a nonmoving target, the phase differences can be converted into a digital elevation map if very precise satellite orbit data are available.

Typical scales for SAR interferometry application to landslide movements are millimeters to centimeters per orbit cycle of the radar satellite. This orbit cycle can range from 44 days for ALOS and 10 days for TerraSAR-X. Constellation missions such as Cosmo-SkyMed, Sentinel, and RADARSAT constellation mission are reducing the orbits to 1–4 days.

It is clear that InSAR techniques can be used to monitor landslide motion under specific conditions, provided coherence is maintained over the respective orbit cycle. Using data pairs with short perpendicular baselines, short time intervals between acquisitions, and correcting for the effect of topography and atmospheric effects, reliable measurements of surface displacement can be achieved. The InSAR deformation maps provide linear motion at the line of site. Although this is very useful information, landslide motion is very complex with nonlinear vectors. Therefore, InSAR techniques do not provide the complete 3d motion

Vegetation decorrelates the radar signals. Therefore, stable coherent targets such as installed corner reflectors or man-made constructions such as houses, roads, and bridges are used to calculate the landslide motion. The uses of installed field corner reflectors are increasing on remote vegetated sites. Acquiring about 30 InSAR images on coherent targets over long periods are analyzed by a Permanent

Landslides, Figure 4 Frank Slide, Canada: monitoring landslide motion from RADARSAT InSAR (2000–2010) (Modified from Mei et al. 2007).

Scatterer Technique PSInSAR™ developed by Ferretti et al. (2001). With the Permanent Scatterer Technique, the movement of small objects (down to about 1 m²) can be monitored. This method has been applied to map subsidence and slow-moving landslides and many parts of the world.

The *Frank rock avalanche* is provided to demonstrate the capability of InSAR to monitor gradual motion on large rock avalanche in the Canadian Rockies. The Frank Slide, a 30 × 106 m³ rock avalanche of Paleozoic limestone, occurred in April 1903 on the east face of Turtle Mountain in southern Alberta, Canada. Seventy fatalities were recorded. This slide is still active. Several factors contribute to this rock avalanche. These include the geological structure of the mountain, subsidence from coal mining at the toe of the mountain, blast-induced seismicity, above-average precipitation in years prior to the slide, and freeze-thaw cycles (Cruden and Hungr, 1996). GPS stations and several in situ monitors are installed to monitor post-slide activity at specific

locations (Figure 4). Current InSAR monitoring is complementing the in situ measurements. The fact that the rock covering the rock avalanche is bare and dry leads to the high coherence and identification of more than 95 % of the coherent target monitoring targets for the Frank Slide area. Due to their great density and excellent coverage, the coherent target measurements of this area are a reliable reflection of current deformation pattern. The most recent InSAR results (Figure 4) have shown that during a period from April 2004 to October 2006, the foot of the eastern slope of Turtle Mountain, the ground surface above the coal mine, was found to subside at an average rate of about 3.1 mm per year supporting the speculation that underground coal mining triggered the Frank landslide (Mei et al., 2007).

The above examples show that satellite images are providing reliable complementary techniques to landslide mapping and monitoring, and therefore, its uses are increasing in landslide investigation and mitigation.

LAW OF REMOTE SENSING

Joanne Irene Gabrynowicz

National Center for Remote Sensing, Air, and Space Law,
The University of Mississippi School of Law, Mississippi,
MS, USA

Overview

All of the international space law began with the Declaration of Legal Principles Governing the Activities of States in the Exploration and Use of Outer Space (Declaration), adopted in 1962 by the United Nations General Assembly. National space laws, like that of the United States, were influenced by international space law and developed in tandem.

The Declaration is the foundation for the Treaty on Principles Governing the Activities of States in the Exploration and Use of Outer Space, including the Moon and Other Celestial Bodies (Outer Space Treaty). The Outer Space Treaty entered into force at the height of the Cold War on October 10, 1967. It contains fundamental space

law principles that are directly applicable to remote sensing activities, such as all nations have the nonexclusive right to use space. In less than a decade, four more treaties followed, some of which also have legal principles applicable to remote sensing.

Legislative history in the United Nations

In 1970, Prof. A.A. Cocca of Argentina first introduced remote sensing as a specific legal topic in a paper to the Legal Subcommittee of the U.N. Committee on the Peaceful Uses of Outer Space (UNCOPUOS). In 1971, a Working Group was formed in the Legal Subcommittee to consider the paper, and in 1973, the Scientific and Technical Subcommittee of UNCOPUOS issued its first report containing a section on remote sensing. In 1974, the General Assembly adopted a resolution recommending that the LSC should consider the question of the legal implications of remote sensing of the Earth from space.

In 1975–1976, the first discussions concerning the legal implications of remote sensing began. Initially, the participating Nation-States organized themselves into three groups, or blocs: the Soviet Union/East Europe; the Group of 77 (G-77), consisting of developing nations in Africa, Asia, and Latin America; and the Western Group. The primary issues were whether or not sensing States had to obtain the consent of a sensed State prior to acquiring data from space or prior to distributing data to a third party. The Soviet Union and France submitted a proposal to require sensing States to obtain the prior consent of sensed States before data could be made available to other entities. The G-77 initially opposed both remote sensing itself and the distribution of data. The United States, then the only sensing state, advocated a free flow of data and therefore opposed prior constraints.

In 1975, the General Assembly recommended that the Legal Subcommittee continue consideration of remote sensing from space as a high priority. It specifically pointed to the use of remote sensing regarding the Earth's natural resources and environment. It also recommended drafting principles regarding points on which States agreed. The General Assembly noted that the Scientific and Technical Subcommittee had examined operational and experimental questions and now recommended that studies be conducted on organizational and financial matters. It also endorsed an international remote sensing training center for personnel from developing nations. In 1976, this work slowed down because the Soviet Union attempted to link some remote sensing issues to the developing Moon Treaty. By late 1976, progress was made on formulating some draft principles. The General Assembly noted in a resolution that the Legal Subcommittee formulated five draft principles and identified three new common elements identified by States.

Main issues

From 1977 to 1979, the Working Group focused on three main issues: whether or not “should” or “shall” ought to

be used in the principles, providing consultation and dispute resolution procedures, and the Soviet Union's proposal to limit image gathering to 50 m spatial resolution. Cold War politics drove the legal debate. A specific attempt to codify the 50 m limit was made on May 19, 1978, when Cuba, Czechoslovakia, the German Democratic Republic, Hungary, Mongolia, Poland, Romania, and the Union of Soviet Socialist Republics signed the Convention on Transfer and Use of Data of Remote Sensing of the Earth from Outer Space in Moscow. It provided that if a Contracting Party was in possession of data with resolution higher than 50 m, it was forbidden from making the data available to anyone without the explicit consent of the sensed State. This did not significantly influence the Legal Subcommittee negotiations. In a 1979 resolution, the General Assembly again recommended that the Legal Subcommittee continue work on the draft principles on a priority basis.

The evolution and use of the US *Landsat* system catalyzed addressing many general and specific remote sensing issues in legal terms. In 1982 and 1983, as a cost recovery method, the United States raised the access fee for a *Landsat* ground station from \$200,000 (US) to \$600,000 (US), and the cost of computer-compatible tapes increased. The United States announced its intention to commercialize the *Landsat* system. Identifying principles regarding [data access](#), among others, became more pressing. In 1981, 1982, 1983, and 1984, the General Assembly adopted resolutions that noted each year's progress toward developing principles and continued to urge the Legal Subcommittee to develop the legal implications of remote sensing on a priority basis.

In 1984, the US Congress passed the Land Remote Sensing Commercialization Act (Commercialization Act). It adopted the nondiscriminatory access policy forged in the Legal Subcommittee and provided for a three-phased process to establish commercial remote sensing. The first phase was to award a contract for existing *Landsat* operations to a private sector operator. The second phase was to be a transition period in which both the government and the private sector would operate satellites, with government activities phasing out. The third phase was to be a fully private, commercial environment. The US contract award process had begun and the negotiators in the United Nations took note. Conversely, the United States needed to have the legitimacy of commercial remote sensing activities accepted. France was preparing to launch its first remote sensing satellite, *SPOT-1*, which it did in 1986. In 1984, France proposed alternate language for the draft data access principle, and negotiations on the remote sensing principles were revitalized.

In 1985, significant portions of the draft principles were still not agreed upon. According to at least one report, the Soviet Union/Eastern bloc did not participate in discussions of Article XII, the data access principle, out of concern that there would be no acceptable solutions for the G-77 nations. Some nations, including Mexico and

Vietnam, believed there was insufficient time to consider the draft text. The General Assembly again adopted a resolution endorsing the Legal Subcommittee's work and added that it should finalize the draft set of principles. The Chair of the Working Group was Austria, and it offered an alternate text based on consultations regarding the French proposal. Discussions on the Austrian text were held. No changes were made in 1986. On December 3, 1986, The Principles Relating to Remote Sensing of the Earth from Outer Space (Principles) were adopted by the General Assembly.

The principles relating to remote sensing of the Earth from outer space

The Principles embody the view that Outer Space is a resource for all humanity and should be used for the general benefit of all nations. They encourage international cooperation and address access and distribution of data and information generated by national civilian remote sensing systems. Primary data are the raw data delivered in the form of electromagnetic signals, photographic film, magnetic tape, or any other means. Processed data are the products resulting from processing primary data, and analyzed information means information resulting from interpreting processed data. Remote sensing activities include operations, data collection, storage, processing, interpretation, and dissemination.

The Principles set a standard of international cooperation among sensing and sensed States while attempting to achieve a balance between their rights and interests. Needs of developing nations are given special regard. The Principles specifically promote protection of the Earth's environment and of humanity from natural disasters. States that possess remotely sensed information useful for averting harmful phenomena are required to disclose the information to concerned States. If the potential harm threatens people, the obligation to disclose requires promptness and extends to processed data and analyzed information.

The rights and responsibilities of sensed and sensing States are particularly addressed in Articles IV and XII. Article IV sets a legal standard for behavior among sensed and sensing States, and Article XII is a data dissemination statute. Together, they provide a fluid legal regime that obliges sensing States to avoid harm to sensed States and to provide them with access to primary data and processed data concerning their own territory on a nondiscriminatory basis. This was the compromise between terrestrial sovereignty and the freedom to use space. The legitimacy of space-based remote sensing was accepted by ensuring that a sensed State would have access to the imagery of its territory. Analyzed information available to sensing States is also to be available to the sensed States on the same basis and terms. In turn, sensed States are to meet reasonable cost terms and do not have access to analyzed information legally unavailable to the sensed States, for example, proprietary information.

The Principles were contained in the first major resolution to emerge from COPUOS in more than a decade and provide a foundation for the continued evolution of international remote sensing law. The question of whether or not the remote sensing principles ought to become a treaty continues to be raised in the COPUOS Legal Subcommittee.

US law: The oldest national remote sensing law

On October 28, 1992, the US Congress passed the Land Remote Sensing Policy Act of 1992 (Policy Act). It replaced the 1984 Commercialization Act. Congress adopted the nondiscriminatory access policy for second time. The Policy Act's focus is long-term remote sensing policy and its numerous facets. Specific matters addressed include program management, *Landsat 7* procurement, *Landsat 4* through *7* data policy, transfer of *Landsat 6* program responsibilities, regulatory authority and administration of public and private remote sensing systems, federal research and development, advanced technology demonstration, *Landsat 7* successor systems, data availability and archiving, and the continued prohibition of weather satellite commercialization. The legislation features a focus on the value of remote sensing in conducting global change research and other public sector applications, a recasting of remote sensing activities, and provisions for the future evolution of remote sensing policy. In 2008, efforts were made to replace the 1992 law with a new statute titled, the *National Land Imaging Program*. This bill was intended to embody the US new national remote sensing policy to implement a long-term operational land imaging program. It was not made into law.

New law and policy of remote sensing nations

India, the United Kingdom, and some other remote sensing nations have policies rather than laws. However, increasingly, major remote sensing nations are promulgating national laws. In 1999, Canada announced a policy that, in 2005, received Royal Assent and which came into force in April of 2007 as the *Remote Sensing Space Systems Act*. In 2007, the *German Act on Satellite Data Security* entered into force. These laws address the commercial availability of high-resolution imagery, and both seek to ensure national security interests within a commercial context. In 2008, Japan and France each passed a comprehensive national space law that includes sections on remote sensing. Court decisions in France, Germany, and the United States regarding the intellectual property and other aspects of remote sensing are also adding to the overall corpus of law.

Globalizing Earth observations

In the 1990s, the trend to internationalize Earth observation satellite operations began, and important new agreements were formulated. On November 19, 1998, the US National Oceanic and Atmospheric Administration and

the European Organisation for the Exploitation of Meteorological Satellites entered into an agreement on a joint polar-orbiting operational system, and a second agreement was entered into on June 24, 2003. *The International Charter on Space and Major Disasters* became operational on November 1, 2000. Some nations, like Belgium, do not have indigenous remote sensing capabilities but, nonetheless, are developing national remote sensing laws because they are participating in remote sensing consortia. It is clear that remote sensing law will continue to develop.

LIDAR SYSTEMS

Robert Menzies
Jet Propulsion Laboratory, California Institute of
Technology, Pasadena, CA, USA

Synonyms

Ladar; Laser radar

Definitions

Lidar. Light Detection And Ranging
Ladar. LAser Detection And Ranging

Introduction

A lidar system in the strictly defined sense of the acronym measures range to a “target” that provides a signal that can be detected. Thus, the lidar system includes both a transmitter and a receiver. Ranging is accomplished using time-of-flight methods. The target can be a “hard” target that is essentially opaque to the lidar wavelength, not allowing measureable penetration beyond its range, or a “diffuse” scattering medium that allows penetration and range gating. Examples of the former are the surfaces of the Earth and other planets, or man-made objects. Examples of the latter are atmospheric aerosols and gases. In reality, these are terms that are commonly used but do not have strict, universally accepted definitions. In fact, the term “lidar” itself is commonly applied to systems that contain transmitters and receivers but do not have inherent range measurement capability. The lidar community is inclusive in this regard.

Following David Tratt’s introductory entry (“Emerging Technologies: Lidar”), which describes lidar basics and various classes or categories of lidar, we provide here a summary of the current capabilities in these various lidar applications areas. Our lidar categories are altimetry and mapping systems, backscatter systems, Doppler systems, and differential absorption systems. Comments on emerging technologies and methods are included. Lidar/ladar applications cover a wide range of activities and interests. The 3D imaging applications are a growth area with strong support from the defense community. System developments in this area are included only in brief overview mode. The balance in this entry is tilted more toward systems developed for scientific investigations.

Altimetry and mapping systems

Laser altimetry is relatively mature, with heritage in aircraft instruments, followed by Earth-orbiting, Mars-orbiting, and Lunar-orbiting systems. The early altimeter/mapping instruments used a form of threshold detection to trigger a circuit that enabled range measurement to a “first return” scattering surface. The implementation of fast waveform recovery, or multistop detection circuits, increases data rates but provides structure information in the line-of-sight dimension. The Geoscience Laser Altimeter System (GLAS) on the Earth-orbiting ICESat (Abshire et al., 2005) provided structure detail in the time domain, a capability that is essential for future use of laser 3D mappers in obtaining global estimates of biomass. High-resolution 3D imaging with very high depth resolution (~ 1 mm) can be achieved at km distances using fiber lasers and high bandwidth waveform encoding and decoding techniques (Buck et al., 2007). The current and next-generation systems combine multi-beam transmitter patterns with structural detail in the range dimension. The laser altimetric observational method provides line-of-sight detail that complements radar methods as well as higher spatial resolution in the cross dimensions. Spatial coverage is

a challenge, however. The advent of avalanche photodiode (APD) arrays and photon-counting receivers (e.g., Aull et al., 2002; Albota et al., 2002), combined with optical methods for simultaneous transmission of multiple beams, have greatly increased the mapping efficiencies of airborne and space systems. The use of statistical methods in a photon-counting mode has allowed the use of compact, high pulse-repetition frequency (prf), low pulse energy laser transmitters in various imaging and mapping systems (Degnan et al., 2008; Steinvall et al., 2008). The Lunar Orbiter Laser Altimeter (LOLA) instrument, scheduled to launched in June, 2009, uses a Diffractive Optical Element (DOE) to produce a 5-beam pattern for provision of more spatial coverage than with prior space laser altimeters (Ramos-Izquierdo et al., 2009; Smith et al., 2010). The DOEs have found use in various airborne laser 3D mappers.

An alternative to the use of scanners or elements such as DOEs, matched with APD arrays, is a flash lidar/ladar. The images in this type of system record the intensity reflected by the scene when flood-illuminated by the laser transmitter pulse. The laser transmitter irradiates the entire field of view of the receiver camera pixel array, and each pulse generates an entire frame of data (Stettner et al., 2005). The array elements are high-speed detectors that are periodically sampled in time at nanosecond timescales. The advances in hybridizing the focal planes with silicon CMOS read-out integrated circuits (ROICs), utilizing steady improvements in high-speed circuitry, provide the potential for growth with this approach. Laser sources can include semiconductor lasers and fiber lasers mated to power amplifiers.

Backscatter lidars

Here we include elastic backscatter lidars and various types of inelastic backscatter lidars (e.g., Raman, fluorescence). The emphasis is on atmospheric studies using these systems. The intensity or energy in the return signal is important with backscatter lidar measurements. Some method of calibration and/or normalization must be used in order to turn the data into useful observations. In the visible, the molecular density, if known sufficiently well, can be used to provide a Rayleigh backscatter intensity that effectively calibrates at least the range dependence of the lidar efficiency factor, or the efficiency factor itself at a particular atmospheric altitude where particle scattering is assumed negligible. This is not a viable technique at longer wavelengths in the infrared, due to the rapid decrease of the Rayleigh scattering cross section with increasing wavelength.

Backscatter lidars for cloud and aerosol studies date back to the early years of lidar, when ground-based lidars operating at visible wavelengths probed the stratospheric aerosol layers (e.g., Fiocco and Grams, 1964). The first Earth-orbiting lidar used for atmospheric studies was an elastic backscatter lidar (LITE, launched in 1994). GLAS operated both as an altimeter and an atmospheric lidar

(Spinhirne et al., 2005). Currently the CALIPSO lidar is in Earth orbit, being used for cloud and aerosol studies. The CALIPSO transmitter is a diode-array pumped Nd: YAG laser, by far the most commonly used in backscatter lidars. A wide dynamic range of pulse energies and pulse-repetition frequencies are available in this laser medium. The compact micropulse lidars, which emit pulses in the micro-Joule range, are deployed around the globe in networks such as the MPLNET (Micropulse Lidar Network) (Campbell et al., 2008). Cloud and aerosol detection, characterization, and monitoring algorithms continue to improve for these compact lidars, making them more useful for deployment. The underlying technologies are robust. The vertical profiling capabilities of these lidars cannot be duplicated with passive instruments. Recently, a compact backscatter lidar was deployed on the surface of Mars as part of the Phoenix mission (Whiteway et al., 2008).

A variant of the elastic backscatter lidar that is taking center stage in current and future atmospheric investigations is the High Spectral Resolution Lidar or HSRL. Although Doppler lidars are the ultimate high spectral resolution lidars, the term “HSRL” is commonly used in the lidar community to refer to a system that can separate the molecular Rayleigh backscatter signal from the aerosol backscatter signal. This obviates the need to assume a “lidar ratio” (i.e., aerosol extinction-to-backscatter ratio) when interpreting the range-dependent backscatter signals to deduce aerosol optical properties, thereby achieving more robust estimates of aerosol extinction coefficients. A progression in HSRL implementation has gone from early 1980s laser technology such as fragile dye laser systems (Shipley et al., 1983) to more robust solid-state lasers (Grund and Eloranta, 1991). Iodine vapor filters offer simplicity compared with the etalon filters in the HSRL receiver (Hair et al., 2001). More recently, airborne HSRL has been developed, and measurement results have been reported (Hair et al., 2008). The next-generation Earth-orbiting backscatter lidar for cloud and aerosol studies will likely be an HSRL. In fact, the European Space Agency’s Atmospheric Laser Doppler Instrument (ALADIN), a Doppler lidar in the Atmospheric Dynamics Mission (ADM) with atmospheric wind field measurements as its primary objective, is fundamentally an HSRL and will be used for investigations of aerosol optical properties (Ansmann et al., 2007) (see www.esa.int for further information).

Resonance fluorescence lidars have been in use for decades to study dynamics and thermal properties of the middle atmosphere, particularly the mesosphere. Lidars built to measure alkalis in the upper mesosphere were also used as Rayleigh backscatter lidars to measure density and temperature profiles in the stratosphere and mesosphere (Hauchecorne and Chanin, 1980). Developments in solid-state laser technology and injection seeding methods have resulted in systems that are more amenable to transportation and operation at remote sites

(e.g., She et al., 2007). Systems that interact with a variety of metals in addition to sodium and the other alkalis are now in development for investigations over a wider range of altitudes (Gardner, 2004).

Raman lidars are now commonly used for water vapor profiling and for characterizing the optical and microphysical properties of atmospheric aerosol. The latter method was described 20 years ago (Ansmann et al., 1990) and has continued to evolve into systems that are being used for characterization of major dust plumes that are transported long distances (e.g., Asian dust, Saharan dust) and for calibration/validation exercises (Mona et al., 2007). The former method has a long history and has slowly evolved with the use of improved techniques for minimizing background light, improved algorithms, and improved understanding of sources of bias. The use of Raman lidar for water vapor profiling in the lower atmosphere continues to gain credibility as the level of accuracy continues to improve (Adam and Venable, 2007; Leblanc and McDermid, 2008).

Doppler lidars

The atmospheric gas molecules and aerosol particles are in bulk motion in the dynamic atmosphere, and backscattering of laser radiation from the molecules and aerosol particles produces Doppler shifts in frequency. Doppler lidars detect these frequency shifts to deduce wind profiles. Two types of Doppler lidar have received attention over the years: direct detection and coherent detection lidars.

The coherent detection lidar is more sensitive and less difficult to implement at relatively longer wavelengths in the infrared, particularly at wavelengths longer than 1.5 μm , the so-called eye-safe region. The ultrahigh spectral resolution that is inherent with these systems makes coherent detection suitable for measuring Doppler-shifted backscatter from the atmospheric aerosol particles. The signal processing has similarities with Doppler radar. The use of rare-earth-doped solid-state laser technologies in the 2 μm wavelength region has been a popular choice for compact coherent detection systems. An example is the NOAA shipborne lidar, which has been used in many field campaigns (Tucker et al., 2009). Airborne systems date back to the mid-1980s when carbon dioxide gas laser transmitters were used (Bilbro et al., 1986). More recent, much more compact systems have also been deployed for measuring wind profiles with high spatial resolution (Hannon et al., 1999). Both the rare-earth-ion-doped solid-state crystal laser technology at 2 μm and the fiber laser technology developed primarily by the telecom industry have been employed in recent ground-based coherent Doppler lidars stationed at airports for airport safety enhancements. These lidar systems are being used for both wake vortex monitoring (e.g., Kopp et al., 2004) and wind shear detection and warning (e.g., Shun and Chan, 2008). Fiber laser

technologies are being incorporated into current and future systems.

Direct detection lidar is the appropriate choice for regions of the atmosphere containing very low aerosol particle concentration in the size range that is useful for optical scattering. The predominant scattering is molecular Rayleigh scattering. An early example was the use of direct detection Rayleigh lidar, modified with the incorporation of twin Fabry-Pérot interferometer filters in the receiver, for measurements of horizontal winds in the middle atmosphere (Chanin et al., 1989). An airborne direct detection Doppler lidar was developed, for tropospheric wind field measurements (Gentry et al., 2007). It is designed for autonomous operation on a high-altitude aircraft. The European Space Agency's ALADIN lidar is planned for launch in 2010, as the centerpiece instrument in the Atmospheric Dynamics Mission (ADM). ALADIN uses solid-state Nd: YAG laser transmitter technology, frequency-tripled to the 355 nm near-UV wavelength. It contains two receivers, one for the narrow-band Mie scattered radiation from the atmospheric aerosol particles (employing a multichannel Fizeau interferometer) and the other for the Rayleigh scattered radiation from the molecules (employing a double-edge Fabry-Pérot etalon). Accumulation CCD's are used in both receivers (see www.esa.int for further information).

Differential absorption lidars

Differential absorption lidars require typically two carefully selected closely spaced transmit wavelengths and a laser transmitter subsystem that has either discrete or continuous tunability in the desired spectral region to interact with the species of interest. Early systems used dye lasers or nonlinear optics such as optical parametric oscillators to provide tunability. Atmospheric ozone and water vapor have been favorite measurement subjects for decades. More recent systems rely on solid-state laser technologies and modern techniques for generating tunable single-mode radiation with high spectral purity. Airborne systems have progressed in sophistication, with corresponding reductions in mass and dimensions as well. The LASE (Lidar Atmospheric Sensing Experiment) system was demonstrated in the 1990s as an autonomous operation water vapor differential absorption lidar on the high-altitude ER-2 aircraft (Browell et al., 1997). Currently, intercomparison campaigns involving multiple airborne water vapor systems with different designs are being planned and implemented in order to better understand the accuracies of measurement and quantify biases that might exist (Behrendt et al., 2007). Results to date show that measurement accuracies are in good agreement with expectations.

Currently, a major challenge for differential absorption lidar is the measurement of atmospheric CO₂. Measurements with very high accuracy over regional to global scales would improve understanding of fluxes between

atmosphere, land surface, and ocean surface. The influence that increasing carbon dioxide mixing ratio has on climate change has spurred an interest in applying both passive and active remote sensing techniques to address this question. Desired mixing ratio accuracy levels of better than 1 % place great demands on a differential absorption lidar system itself and require the minimization of errors due to imperfect knowledge of the relevant atmospheric parameters (Menzies and Tratt, 2003; Ehret et al., 2008). Demonstrations of CO₂ mixing ratio measurement capability using ground-based, coherent detection systems have been reported (Gibert et al., 2008; Koch et al., 2008). Airborne systems are now being tested in flight campaigns, using both the solid-state 2 μ m laser technology and the 1.6 μ m fiber laser technology (Abshire et al., 2010; Spiers, et al., 2011). Studies of Earth-orbiting lidar systems for CO₂ measurements are being conducted under the sponsorship of European, US, and Japanese space agencies (ESA, NASA, and JAXA respectively).

Summary

Using an unofficial taxonomy of lidar systems, selected highlights of recent developments and future plans have been provided. Generally speaking, the future applications for altimetry and three-dimensional mapping will motivate increases in coverage within a given available time frame. This will most likely come from increases in total laser transmitter output power, along with optical technology. In other lidar application areas, engineering advances will be critical. For example, advances in compactness, electrical power efficiency, autonomy, and reliability will be essential for further use in hazard detection and monitoring, as well as expansion of regional and global networks for weather, climate, atmospheric composition, and environmental monitoring. Atmospheric greenhouse gas measurements, on a global scale, present high-precision measurement challenges. Nearly 50 years after the first demonstration of the laser, many lidar system applications are still driven by laser technology advances. For example, many applications still await the development of a wider range of laser sources in infrared spectral regions that are presently underutilized. The advent of the quantum cascade laser and other "bandgap-engineered" semiconductor laser technologies, as well as fiber laser/amplifier technologies, are good examples of continuing laser technology advances.

Synonyms

Cloud flash; Ground flash

Definition

Lightning or *lightning discharge*. A series of transient and multiple electrical breakdown pulses producing high-current channels (Uman, 1987).

Lightning flash. A luminous manifestation accompanying a sudden electrical discharge which takes place from or inside a cloud or, less often, from high structures on the ground or from mountains (WMO, 2011).

Introduction

A lightning flash is a noncontinuous multi-scale physical process that ranges from the initial breakdown of air to the actual discharge propagation in discrete steps that can occur from cloud to ground (CG) or inside the clouds, i.e., intracloud (IC). In the case of CG lightning, the lightning channel formation is led by *stepped leaders* (that creates a conducting path between charge centers) and then followed by one or multiple *return strokes* that traverse the channel moving electric charges and neutralizing the leaders (Rakov and Uman, 2003). These series of return strokes are the lightning flash, and each stroke is guided by the *dart leaders* that propagate downward on the track of a preceding return stroke. CG flashes are also classified by the polarity of lowered charge: negative and positive. Negative flashes are more common and exhibit several return strokes, while positive flashes have a single or very few return strokes, but higher current than the negative ones. These processes occur too rapidly for the human eye to distinguish, and the flash appears as a single channel lasting for less than a second. Lightning detection networks typically look for the electric field changes associated with such processes. In the case of IC lightning, *recoil streamers* propagate within the track of positive branches of a bi-leader carrying strong negative charges. The lightning flash is terminated when the electric field is reduced to the point where it cannot sustain the discharge's propagation anymore.

The electromagnetic spectrum of lightning

The rapid release of electric energy inside the lightning channel generates a shock wave and electromagnetic radiation in a broad spectrum, see the entry [Radiation, Electromagnetic](#). The shock wave rapidly decays into an acoustic wave we know as thunder. The electromagnetic radiation ranges from radio frequencies through visible to X-rays and gamma rays, composing the basis for ground-based lightning location systems (LLS) and remote sensing from satellites.

Each lightning component (stepped leaders, return strokes, recoil streamers) emits electromagnetic energy proportional to the charge carried and its derivative in time. Negative stepped leaders are associated with strong negative currents in very short pulses (1 ms) and are detectable in very high frequencies (VHF, 1–200 MHz), as well as the dart leaders and recoil streamers, but with a relatively lower electrical current (MacGorman and Rust, 1998). The return strokes of a CG are high-energy discharges typically of the magnitude 10–100 kA in long pulses and radiate from the very low to high frequency range (1 kHz–10 MHz). Positive CG return strokes usually have continuous high current (>100 kA) and therefore are easily detected by VLF systems.

Radio emissions from lightning occur in the form of short pulses by accelerated charges during the fast-changing current steps, while the optical emissions occur from ionized and dissociated gases by thermal radiation of the lightning channel (Goodman et al., 1988). The heating in the channel reaches temperatures above 20,000 K resulting in optical emissions primarily in discrete atomic lines with some continuum at shorter wavelengths. Several measurements of lightning emission in the cloud top have shown strongest emissions at the neutral oxygen (OI(I)) and neutral nitrogen (NI(I)) lines, i.e., 777.4 and 868.3 nm in the near infrared, respectively (Goodman et al., 1988).

The radio electromagnetic waves of the lightning processes described above travel through the atmosphere and then are likely to be dissipated, reflected, scattered, refracted, and absorbed. The main effect is the dissipation, reducing the amplitude of the signal inversely proportional to the square of the distance. Ionospheric reflection, where the energy from waves with frequency lower than 5 MHz is trapped in the atmospheric waveguide formed by the ionosphere and the ground, permits long-range propagation of waves from high-energy return strokes. In the optical spectrum, the scattered energy by the cloud particles is observed from satellites as a diffuse light source at cloud top (Christian et al., 1989).

Ground-based lightning location systems

Several instruments can be used to locate lightning flashes, and more detail can be found at MacGorman and Rust, (1998) and Betz et al., (2009). The main technique consists of a network of sensors that detect IC and/or CG lightning by recording the electromagnetic radiation from

VLF to VHF continuously with time. The radiation detected by each sensor is then compared to other sensors in the network using two main location methods: the time-of-arrival and interferometer techniques. In the time-of-arrival method (TOA), time difference of lightning waveforms from several stations is computed and the location of lightning occurrence is given by the intersection of the hyperbolas for equal time differences. The interferometer method consists of determining the directions of the lightning waveform (azimuth and elevation) by analyzing the phase difference of an incident wave at several stations, and the intersection of these directions gives the location of the lightning source.

Today's operational lightning detection networks usually consist of different sensor types that use one or more location method for redundancy. These networks can be local, regional, or global depending on their operation baseline (distance between the sensors), and their detection efficiency and location accuracy are determined by the density of sensors and radio frequency used (Betz et al., 2009). Table 1 summarizes some of these more widely used lightning networks. The largest regional network is the US National Lightning Detection Network (NLDN) created in 1998, composed by 114 sensors operating in LF that locates mainly CG lightning in North America. Similar regional networks are found in Australia, Brazil, Canada, and Europe. Long-range networks operate in VLF and have been deployed worldwide in an attempt to locate lightning over remote areas like the oceans and the tropics. These networks operate with a sensor baseline of thousands of kilometers, which limits the detection efficiency to the stronger amplitude lightning signals (Cramer and Cummins, 1999).

Total lightning (IC + CG lightning) is monitored using VHF and a combination of LF and VLF or VHF and LF. In the USA, total lightning is monitored by several VHF Lightning Mapping Array (LMA) research networks (Table 1) developed by New Mexico Tech (Rison et al., 1999). The individual LMA regional networks consist of 10 or more stations extending ~80 km. The LMA measures the TOA of the magnetic peak signals at the different receiving stations to locate the source of impulsive VHF radio signals. Hundreds to thousands of sources per flash can be correlated in space and time, allowing a 3-D or 2-D lightning mapping of the channel over a regional domain of ~200 km.

Lightning detection from space

Several astronauts reported seeing lightning while looking down from space in the 1960s, describing flashes with hundreds of kilometers in extent and simultaneous flashes occurring between widely separated storms. Lightning was detected in early satellite imagery (Sparrow and Ney, 1971), and in 1981, the space shuttle astronauts recorded lightning in a 16 mm movie camera (Goodman et al., 1993). Although it was not their primary objective, several instruments onboard of the US Air Force DMSP

(Defense Meteorological Satellite Program) satellites have also recorded lightning, providing the first global lightning distribution map as a bonus to the mission (Goodman et al., 1993).

The Optical Transient Detector (OTD) onboard of the Microlab-1 (later renamed as OrbView-1) satellite was the first instrument designed to measure lightning from space day and night with storm scale resolution. The OTD operated between 1995 and 2000 in a 70° inclination low Earth orbit (see Low Earth Orbit (LEO)) at an altitude of 740 km. From this altitude, the OTD observed an individual storm for about 3 min. The design concept was based on the earlier research on optical emissions of lightning at cloud top (Christian and Goodman, 1987; Goodman et al., 1988). The OTD detected optical impulses with a 128×128 charge-coupled device (CCD) using a 1 nm narrow-band interference filter centered at 777.4 nm (Christian et al., 2003). Whereas the earlier satellite-based studies were limited to detecting visible lightning flashes during the darkness of night, the near-infrared wavelength combined with the use of spatial and temporal filtering used by OTD also allowed lightning detection during daylight. In 1997, the Lightning Imaging Sensor (LIS) onboard the Tropical Rainfall

Measuring Mission (TRMM) (Kummerow et al., 1998) was launched into a lower orbit inclination of 35° at an altitude of 350 km, later raised to 402 km in August 2001 to extend the mission lifetime. From this altitude, the LIS observed an individual storm for about 90 s.

The OTD was a flight qualified engineering model of the LIS, and thus, they share the same basic design heritage. In both OTD and LIS, the signal is read out from the focal plane into a real-time event processor for lightning event detection. The background scene is updated during each frame readout sequence and when a pixel's brightness compared to the prior background values exceeds a threshold, it is identified as a lightning *event*. The events are sent to the satellite ground station for geolocation processing in space and time, and an algorithm clusters the events into "flashes" (multiple CCD events grouped into time and space). The flash cannot be distinguished between CG and IC lightning, although in a statistical sense, the fraction of CG and IC flashes might be retrievable from a large sample of flashes (Koshak, 2010).

FORTE (Fast On-Orbit Recording of Transient Events) satellite was built by Los Alamos National Laboratory to study lightning signals from space (Jacobson et al., 2000,

Lightning, Figure 1 Total lightning climatology derived from OTD (1995–2000) and LIS (1998–2010) at 0.5° resolution.

Suszcynsky et al., 2000; Hamlin et al., 2009). Launched in August 1997 at 800 km of altitude with a 70° of inclination and a circular orbit, the optical lightning location system has the same design of OTD and LIS but it also carries a broad band photo diode and the VHF receivers had two broad band channels which are selectable from a grid covering the entire high frequency and to very high frequency (Hamlin et al., 2009), allowing a combined optical and radio frequency observations of lightning. FORTE demonstrated that lightning can be located from space based on multiple-satellite VHF receivers. The “ORAGE” project has also been studying the possibility of locating lightning flashes using VHF-UHF interferometry from a constellation of microsatellites (Bondiou-Clergerie et al., 1999).

OTD and LIS findings

The first global distribution of total lightning was derived from 5 years of OTD measurements by Christian et al., (2003), who found that the annual average global flash rate is 44 fl s⁻¹, with a maximum of 55 fl s⁻¹ in the boreal summer and a minimum of 35 fl s⁻¹ in the boreal winter. Recently, Blakeslee et al. (2012) and Cecil et al. (2012) found that these values remained nearly the same combining OTD (1995–2000) and LIS observations (1998–2010). These authors also showed that all continents display a strong diurnal variation with lightning peaking in the late afternoon, while oceans exhibit a

minimal nearly flat diurnal variation, but morning hours are typically slightly enhanced over afternoon. In Figure 1, we present the updated LIS/OTD climatology for 16 years of OTD (1995–2000) and LIS (1999–2010) combined observations of total lightning flash rate density (FRD, fl km⁻² year⁻¹) from Marshall Space Flight Center gridded LIS-OTD climatology product (High Resolution Flash Climatology, HRFC_COM_FR - Cecil et al. 2012). The difference between land and ocean can be clearly observed, with lightning occurring more frequently over continental (> 20 fl km⁻² year⁻¹) regions having greater instability and stronger vertical motion than oceanic environments. However, some coastal regions presented moderate FRD (1–10 fl km⁻² year⁻¹) associated with frequent synoptic scale extratropical cyclones and cold fronts (such as south-southeast coasts of Brazil, South Africa, Australia, and United States), and large-scale convergence zones (such as the South Atlantic, South Pacific, and the Intertropical Convergence Zones).

High elevated and complex terrain regions over the tropics can be identified by high thunderstorm activity (> 30 fl km⁻² year⁻¹) at the mountains foot (e.g., Andes, Himalayas, Sierra Madre Occidental, Cameroon Line, and Mitumba Mountains). Congo Basin is dramatically highlighted by its extensive area of large FRD (> 50 fl km⁻² year⁻¹), where the greatest annual number of individual thunderstorms is observed (Zipser et al., 2006). However, higher resolution (0.10°) LIS climatological maps highlighting topographical features and complex

terrain indicate the Congo Basin has the second highest climatological FRD, with $232 \text{ fl km}^{-2} \text{ year}^{-1}$ (at the foothills of Mitumba Mountains), while the total lightning “hot spot” on Earth is observed over Lake Maracaibo with $250 \text{ fl km}^{-2} \text{ year}^{-1}$ (Albrecht et al., 2011). Lake Maracaibo thunderstorm activity is very localized, determined by nocturnal convergence of land-lake and mountain-valley breezes over a warm lake, building the perfect scenario for thunderstorm development of more than 300 days per year (Albrecht et al., 2011). Frequent lightning activity ($30\text{--}50 \text{ fl km}^{-2} \text{ year}^{-1}$) is also observed over Florida, Cuba, and Indonesia-Malaysia due to land-ocean sea breezes and over the borders of Argentina, Paraguay, and Brazil where the greatest individual flash rates per mesoscale convective systems are observed (Cecil et al., 2005; Zipser et al., 2006).

In addition to mapping the lightning distribution, the instrument suite on the TRMM satellite allows more detailed characterization of the thunderstorms producing lightning. The TRMM radar and radiometer (see [Micro-wave Radiometers](#)) also show more intense storms over land (Cecil et al., 2005; Zipser et al., 2006). But for a given radar or radiometer signature, a storm over land is likely to produce more lightning than an otherwise similar storm over ocean (Liu et al., 2011). This suggests differences in the mixed phase microphysics and precipitation, hinted at by lightning but not resolved by the radar or radiometer uniquely by themselves.

More information on LIS and OTD can be found at <http://thunder.msfc.nasa.gov/>.

The future of lightning mapping from space

The next generation of NOAA Geostationary Operational Environmental Satellite (GOES-R) series and the EUMETSAT Meteosat Third Generation (MTG) will detect, locate, and measure continuous total lightning activity over their full disk with a nominal resolution of 10 km. GOES-R will carry the Geostationary Lightning Mapper (GLM) and it is scheduled to be launched in late 2015, while the MTG will carry the Lightning Imager (LI) and it is scheduled to be launched in 2018. Both GLM and LI are heritages of OTD and LIS, but GOES-R and MTG are equipped with improved communications systems and much greater telemetry bandwidth to ensure a continuous and reliable flow of the remote sensing products. The GOES-R series will maintain the 2-satellite system over the western hemisphere, with the operational GOES-R satellites at 75°W and 137°W . The GLM and LI together will provide continuous full-disk total lightning for storm warning and nowcasting (e.g., early warnings of tornadic activity, hail, and floods – see [Severe Storms](#)) for half of the globe. A geostationary lightning imager (GLI) having more limited coverage of mainland China and adjacent ocean is also planned for the Chinese FY-4 next-generation geostationary satellite series. More information on GOES-R GLM and MTG-LI can be found at <http://www.goes-r.gov/> and <http://www.eumetsat.int/>, respectively.

Definition

Limb. The portion of a planetary (or stellar) atmosphere at the outer boundary of the disk, viewed “edge on.”

Limb sounding. Atmospheric remote sounding technique involving observing radiation emitted or scattered from the limb.

Occultation. Atmospheric remote sounding technique involving observing radiation emitted (or reflected) by a distant body (solar, stellar, lunar, or an orbiting satellite), transmitted along a limb path through an absorbing and/or scattering planetary atmosphere, and detected by a remote observer.

Introduction

Limb sounding is a widely used atmospheric remote sounding technique, whereby the atmosphere is viewed “edge on” by a space- or airborne instrument. Limb sounding observations are made from the microwave and infrared – where thermal emission is observed – to the visible and ultraviolet, where observations are typically of sunlight scattered in the limb or of airglow. A wide range of spaceborne limb sounding instruments have been used to observe atmospheric temperature, composition, and dynamics from the upper troposphere (~10 km altitude) to the mid-thermosphere (~450 km). A closely related technique, known as “occultation,” involves observing the atmospheric absorption and/or scattering of radiation emitted by a remote source (solar, lunar, stellar, or, more recently a GPS satellite).

Limb sounding has significant advantages over nadir sounding (i.e., viewing straight down) or near-nadir sounding. Firstly, scanning the instrument field of view vertically across the atmospheric limb can give atmospheric profile information with greater vertical resolution than is typically possible from nadir sounders. In addition, complexities associated with emission or reflection of radiation by the planetary surface can be avoided. Finally, by viewing a significantly longer atmospheric path than nadir sounders, limb viewing instruments can achieve a stronger signal to noise for observations of tenuous atmospheric trace gases. However, this same long path length (typically a few 100 km) results in a poorer horizontal resolution than is possible with nadir sounding instruments.

With the exception of the infrared Mars Climate Sounder instrument (MCS, McCleese et al., 2007) on the Mars Climate Orbiter, limb sounding observations have been confined to those of Earth’s atmosphere and are the focus of the discussion in this entry.

Principles and techniques

Limb radiances and line broadening

Each limb view is associated with a particular “tangent height” – the closest distance from the limb ray to the Earth’s surface. High tangent height views typically give small signals, due to the tenuous atmosphere at these altitudes. As tangent altitudes decrease, atmospheric emission or scattering strengthens, increasing the observed signals. Eventually, the atmosphere becomes sufficiently opaque that signals from lower regions in the atmosphere are absorbed by the layers above and not seen by the instrument. At this point, radiances tend to remain fairly constant with decreasing tangent altitude (or to change only slightly, due to second-order geometrical effects) and are said to be “saturated” or “blacked out,” as the signal continues to derive largely from the lowermost nonopaque layers. Refraction is significant for limb rays in the lower atmosphere but is generally negligible above ~20 km.

Molecular spectral lines are broadened in the atmosphere by a combination of the ensemble of Doppler shifts from the thermal motion of the molecules (“Doppler” broadening) and by collisions with other molecules (“collision” or “pressure” broadening). The latter generally dominates line widths of infrared and microwave signals up to ~ 60 km, while for visible and ultraviolet wavelengths, Doppler broadening dominates throughout the bulk of the atmosphere. Pressure broadening of spectral lines can provide valuable information on the vertical distribution of trace gases (in addition to the information gained by vertically scanning the instrument field of view) with frequencies further from line centers conveying information on lower regions of the atmosphere, where lines are broad enough to contribute to the observed signals. For wavelengths where pressure broadening is insignificant, vertical distribution information can still be obtained by observing in multiple spectral regions having different atmospheric absorptions (and thus penetration depths).

Solar occultation and related observations

Observation of the atmospheric absorption of solar radiation (“direct sun” measurements) has a long heritage in atmospheric science (e.g., the observations of ozone pioneered in the 1920s by Dobson). Solar occultation is a natural extension of these ground-based techniques (and similar observations from balloon and aircraft vantage points). An instrument on a low Earth-orbiting spacecraft can perform an occultation observation during sunrise and sunset on each of ~ 14 orbits per 24 h period. Typically, occultation instruments observe a narrow portion of the solar disk and track this as it rises or sets through the atmosphere. The strong solar signal provides excellent signal to noise and obviates the need to cool the instrument or its detectors. The observations of the sun above the atmosphere, before sunset or after sunrise, can be used to ensure a stable instrument calibration.

A succession of solar occultation instruments have provided a long record of atmospheric composition observations including the Stratospheric Aerosol and Gas Experiment (SAGE) I, II, and III series of instruments (McCormick et al., 1989), the Polar Ozone and Aerosol Measurement (POAM) instruments (Lucke et al., 1999), and the Halogen Occultation Experiment (HALOE) on the Upper Atmosphere Research Satellite (UARS) (Russell et al., 1993). Occultation observations were also made by the Atmospheric Trace Molecule Spectroscopy (ATMOS) instrument flown on the Space Shuttle ATLAS program (Gunson et al., 1996), and the Improved Limb Atmospheric Spectrometer instruments (ILAS I and II) on the Japanese Advanced Earth Observing Satellites (ADEOS I and II). The Scanning Imaging Absorption Spectrometer for Atmospheric CHartography instrument (SCIAMACHY, Bovensman et al., 1999) on the European Envisat performs solar occultation measurements in addition to limb and nadir imaging. Most recently, the

Atmospheric Chemistry Experiment’s Fourier Transform Spectrometer and Measurement of Aerosol Extinction in the Stratosphere and Troposphere Retrieved by Occultation (ACE/FTS and ACE/MAESTRO) instruments have been continuing and augmenting this record (Bernath et al., 2005). Currently, ACE is the only operating mission employing solar occultation, though other concepts are in formulation including plans to fly a SAGE III instrument on the International Space Station.

While offering good vertical resolution and outstanding signal to noise and calibration stability, solar occultation instruments are fundamentally limited by orbital geometry to making only ~ 30 observations per 24 h period. While some instruments augment this coverage with observations of lunar or stellar occultations, these, by definition, have poorer signal to noise than the solar occultation observations.

As described below, limb sounding observations of atmospheric emission or of scattered solar radiation offer comparable vertical resolution to occultation but have the advantage that observations can be made on a near-global basis daily.

Radio occultation

Observations of the atmospheric occultation of signals broadcast by GPS are a more recent development. In this technique, observations of refractive phase shift, as opposed to atmospheric absorption in different spectral regions, form the basis for the measurement. GPS occultation yields information on atmospheric refraction, and in turn temperature and/or water vapor profiles. More information on this technique is given elsewhere in this volume.

Microwave limb sounding

Atmospheric microwave emissions are generally associated with molecular rotational transitions, theoretically enabling observation of any atmospheric species with a significant dipole moment. Microwave limb sounding instruments have made observations of a wealth of species in the frequency range from ~ 60 GHz (5 mm wavelength) to ~ 2.5 THz (120 μm). Microwave signals are unaffected by aerosols and all but the thickest clouds, as the wavelengths used are longer than the typical particle sizes. This enables microwave observations of atmospheric composition in a limb sounding geometry in regions that are too cloudy for observations at other wavelengths.

To date, five spaceborne instruments employing limb sounding at microwave frequencies have flown: The Microwave Atmospheric Sounder (MAS) as part of the ATLAS payload on the Space Shuttle (Croskey et al., 1992), the Microwave Limb Sounder (MLS) instruments on the NASA UARS and Aura satellites (Barath et al., 1993; Waters et al., 2006), the Submillimeter Radiometer (SMR) on the Swedish Odin satellite (Murtagh et al., 2002), and, most recently, the Submillimeter-Wave Limb

Emission Sounder (SMILES) on the International Space Station (Ozeki et al., 2001).

Microwave instruments can achieve arbitrarily fine frequency resolutions, enabling individual transition lines to be resolved in great detail. The observations of line shape enable simultaneous observation of both atmospheric pressure (largely affecting the width of a given transition line in the pressure-broadening regime) and species abundance (largely affecting the line strength). By combining inferred atmospheric pressure information with limb tangent altitude information, and assuming hydrostatic balance, atmospheric temperature profile information can be obtained.

The field-of-view width for a microwave instrument is determined by the antenna size and wavelength employed, with narrower fields of view achieved for larger antennae and/or shorter wavelengths and somewhat large antennae dictated for many observations. For example, the Aura MLS instrument's 1.6 m antenna has a field of view that is ~ 3.5 km wide at the limb (full width, half maximum) at 200 GHz from a 700 km orbit. The lower vertical range of microwave limb sounding instruments is limited by continuum absorption from oxygen, nitrogen, and water vapor, with ~ 8 km altitude typically being the deepest penetration.

Infrared limb sounding

As with microwave limb sounding, infrared instruments observe thermal emission from the atmosphere, in this case mostly arising from molecular vibrational transitions. Again, collisional broadening enables determination of atmospheric pressure at the tangent point. Although not all infrared limb sounding instruments have the spectral resolution to resolve individual line shapes, pressure information can generally still be obtained from broader-band measurements.

Scattering and emission from clouds pose a more significant limitation to infrared limb sounders than microwave instruments, particularly in the tropics where clouds are prevalent in the upper troposphere. In clear-sky regions, infrared limb sounders can typically penetrate a few kilometers deeper than microwave sounders, but continuum absorption is, again, the ultimate limitation to this penetration. Infrared instruments can more easily achieve narrower fields of view than those in the microwave, and this can translate into a finer vertical resolution for the geophysical observations. However, the detectors typically need to be cooled (e.g., to ~ 70 K) in order to achieve a scientifically useful signal to noise.

Infrared limb sounding instruments have a long history in atmospheric science, starting with the Limb Radiance Inversion Radiometer (LRIR) on Nimbus 6, followed by the Limb Infrared Monitor of the Stratosphere (LIMS, Gille and Russell, 1984) and Stratospheric and Mesospheric Sounder (SAMS, Drummond et al., 1980) instruments on Nimbus 7. UARS included two infrared limb sounding instruments – the Cryogenic Limb Array

Etalon Spectrometer (CLAES, Roche et al., 1993) and the Improved Stratospheric and Mesospheric Sounder (ISAMS, Taylor et al., 1993). More recent infrared limb sounders include the Michelson Interferometer for Passive Atmospheric Sounding instrument (MIPAS, Fischer et al., 2008) on ESA's Envisat spacecraft and the High-Resolution Dynamics Limb Sounder (HIRDLS, Gille et al., 2008) on NASA's Aura satellite.

The Sounding of the Atmosphere using Broadband Emission Radiometry (SABER) instrument on the Thermosphere, Ionosphere, Mesosphere Energetics and Dynamics (TIMED) mission (Russell et al., 1999) is another recently launched infrared limb sounder mainly focusing on the chemistry and structure of the upper atmosphere.

Visible and ultraviolet limb sounding

Limb viewing instruments at visible and ultraviolet wavelengths generally observe sunlight scattered by the atmospheric limb. These include the Optical Spectrograph and Infrared Imaging System (OSIRIS, Llewellyn et al., 2003) instrument on Odin and the planned limb sensor for the Ozone Mapping and Profiling Suite (OMPS) on the NPOESS (National Polar-orbiting Operational Environmental Satellite System) Preparatory Project (NPP). The SCIAMACY instrument on Envisat also includes a limb scattering capability. As collisional broadening does not significantly affect the (mainly electronic or vibronic) molecular transitions at these wavelengths, tangent pressure cannot be deduced from the observations, and the height registration of the resulting geophysical products is more critically reliant on independent knowledge of spacecraft pointing than is the case for longer wavelength observations.

In addition to limb scattering sounders, past instruments have observed visible atmospheric airglow emissions in the upper atmosphere. These include the Wind Imaging Interferometer (WINDII, Shepherd et al., 1993) and the High-Resolution Doppler Imager (HRDI, Hays et al., 1993) instruments, both on UARS, which used these observations to deduce upper atmospheric dynamics.

Inversion approaches for limb sounding instruments

Although scanning the field of view of an instrument up and down the atmospheric limb enables high-resolution observations of vertical profiles, the observed signals are (as with nadir sounding) affected by emission, absorption, and scattering throughout the ray path. Disentangling the impact of each atmospheric layer on the observed signal and deducing vertical profiles of temperature and composition is a nontrivial task, commonly known as a "retrieval" or "inverse" calculation.

A variety of techniques have been employed for limb sounding retrievals. The so-called onion peeling approach uses observations at the top of the limb scan to characterize the uppermost atmospheric region. This is then

accounted for when characterizing the next layer down, using lower-altitude limb views, and so on. A drawback of this technique is that the resulting profile depends strongly on the knowledge of the uppermost regions, where signal to noise is typically poor.

The most commonly adopted approach for limb sounding retrievals is the well-established “optimal estimation” method (Rodgers, 2000), which seeks the atmospheric state that matches all the observed signals simultaneously (taking into account potential noise on each signal). Although more computationally intensive than simpler approaches, this need not be a barrier with modern computing capabilities. Indeed, the most computationally demanding part of the calculation is typically the “forward model” (the computation that estimates the signal that would be observed by the instrument for a given atmospheric state), which is a central part of all but the simplest retrieval approaches, and upon which the accuracy of the resulting geophysical profiles ultimately depends.

Inhomogeneity along the limb line of sight can introduce biases in limb sounding retrievals, particularly in regions of strong atmospheric gradients. Some retrieval methods employ an iterative approach, whereby horizontal gradient information from a first pass is considered in a later retrieval step. In cases where the instrument line of sight is aligned with the spacecraft velocity vector, successive limb scans take multiple views through the same region of atmosphere, enabling a “tomographic” approach to the retrieval calculation to be taken (e.g., Livesey and Read (2000)).

Notable findings from limb sounding observations

The near-global daily coverage and good vertical resolution of limb sounding instruments has provided a wealth of information on atmospheric structure and composition from the upper troposphere through to the thermosphere. The early observations from LIMS and SAMS set the stage, with zonal-mean information on the abundance of key stratospheric and mesospheric trace gases. The three atmospheric composition limb sounders (CLAES, ISAMS, and MLS) on UARS, along with the HALOE solar occultation instrument, provided valuable insights into the dynamics and chemistry of Earth’s stratosphere, most notably processes associated with chemical **stratospheric ozone** loss and the transport of air into and throughout the stratosphere. UARS observations also provided valuable information on the impact of volcanic gases and the resulting aerosols on the stratosphere, following the dramatic June 1991 eruption of Mt. Pinatubo in the Philippines (4 months before the UARS launch).

In addition to stratospheric and mesospheric composition observations, UARS MLS provided unprecedented information on water vapor and ice clouds in the upper troposphere. The Aura MLS and HIRDLS instruments have enhanced this record providing the first daily global observations of upper tropospheric ozone, carbon

monoxide (MLS only), and nitric acid. The upper troposphere is an important region of the atmosphere for climate, as it is where water vapor (the strongest greenhouse gas) and ozone have their largest radiative impact.

Outlook

At the time of writing, the only limb sounding instruments in operation are Aura MLS, Odin SMR and OSIRS, and Envisat MIPAS. The SMILES instrument experienced a critical failure after ~6 months of operation, although plans are in formulation for a possible fix. While several new limb sounding instrument concepts are under formulation, to date none have been confirmed for launch. The most mature is the ESA Process Exploration through Measurements of Infrared and millimeter-wave Emitted Radiation (PREMIER) mission, which includes infrared and microwave limb sounding instruments observing the upper troposphere and lower stratosphere.

Conclusion

Limb sounding instruments provide a wealth of information on the composition, structure, and dynamics of Earth’s atmosphere, through observations of emitted or scattered radiation in an “edge on” viewing geometry. Limb sounding offers a valuable combination of good vertical resolution and near-global daily coverage, using wavelengths ranging from the microwave to the ultraviolet, and can provide observations from the upper troposphere to the middle thermosphere. Limb sounding observations have led to important discoveries concerning key dynamical and chemical processes in Earth’s stratosphere (including those processes associated with the “ozone hole”), and in the upper troposphere where water vapor and ozone have their strongest greenhouse forcing.

(ISV)

Definition

The MJO is a planetary-scale quasiperiodic oscillation of atmospheric wind and convective cloudiness anomalies that moves slowly eastward along the equator mainly over the tropical Indian and Pacific Oceans with a timescale on the order of 30–60 days.

Introduction

In 1971, Roland Madden and Paul Julian stumbled across a 40–50 day oscillation when analyzing the zonal (east–west) wind data from rawinsondes at Kanton Island (3 °S, 172 °W) over the equatorial western Pacific. Until the early 1980s, little attention was paid to this oscillation, which later became known as the MJO. Since the 1982–1983 El Niño event, low-frequency variations in the tropics, both on intra-annual (less than a year) and interannual (more than a year) timescales, have received much more attention, and the number of MJO-related publications grew rapidly. The MJO turned out to be the dominant form of the intraseasonal (30–90 day) variability in the tropical atmosphere and has many important influences on the global weather and climate system.

The MJO is a naturally occurring mode of variability of the tropical ocean–atmosphere system. It is characterized by an eastward propagation of large regions of both

enhanced and suppressed tropical convection, cloudiness and rainfall near the equator mainly over the tropical Indian and Pacific Oceans, and associated large-scale atmospheric circulation (wind) anomalies over the whole globe. The anomalous cloudiness or rainfall usually first emerges over the equatorial western Indian Ocean and intensifies and remains evident as it propagates eastward over the warm ocean waters of the equatorial eastern Indian Ocean and western Pacific, the so-called Indo-Pacific warm pool. This pattern of anomalous cloudiness and rainfall then generally weakens and disappears as it moves over the cooler ocean waters of the equatorial eastern Pacific, the so-called equatorial cold tongue. Along with this eastward-propagating pattern of equatorial cloudiness and rainfall anomalies, there also exist eastward moving distinct baroclinic patterns of lower- and upper-level atmospheric circulation anomalies in the tropics and subtropics. The circulation anomalies extend around the globe and are not confined to the eastern hemisphere as opposed to the cloudiness and rainfall anomalies. When the MJO moves eastward, it modulates the background cloud, rainfall, and circulation in the tropical Indian and Pacific Oceans on timescales shorter than a season but longer than a couple of weeks. The length of a typical MJO cycle is approximately 30–60 days but normally 40–50 days. Thus, the MJO is also known as the 30–60 day oscillation, 40–50 day oscillation, intraseasonal oscillation (ISO), or intraseasonal variability (ISV) after its typical timescale. A complete MJO cycle can be divided into two distinct phases according to the intensity of its convective activity and rainfall: convectively active (enhanced) phase or wet phase and convectively inactive (suppressed) phase or dry phase. The wet phase of the MJO cycle is characterized by enhanced tropical convection and large moist convective storms with higher cloud-top heights, more cloud cover, and heavier rainfall (thus more atmospheric latent heating)

than average. In contrast, the dry phase of the MJO cycle is typified by dry and clear conditions with lower cloud-top heights, less cloud cover and rainfall (thus less atmospheric latent heating) than normal. The MJO appears to be predictable with lead times of 2–3 weeks. This can help bridge the gap in environmental forecast skill between that of weather (lead times up to a few days) and that of seasonal-to-interannual climate predictions (lead times from a few months to a few years).

Satellite remote sensing data have played an important role in the MJO studies during the last three decades because of the high spatial (a few kilometers) and temporal (3 h or daily) resolutions and global coverage of the satellite data especially over the tropical oceans where the rawinsondes are sparse and the global reanalyses have had large uncertainties. These satellite-based studies have significantly advanced our knowledge in the MJO description and mechanism as well as its global impacts. They have also led to considerable improvement in our numerical modeling capability and theoretical understanding of the MJO. This entry briefly reviews the central role of satellite remote sensing data in studying the description, mechanisms, and global impacts of the MJO.

Description

The MJO and its eastward-propagating convective feature are most active during the Northern Hemisphere (boreal) winter season (November–April) when the Indo-Pacific warm pool is centered near the equator. During the Northern Hemisphere (boreal) summer season (May–October), the change in the large-scale wind patterns associated with the Asian summer monsoon results in the large-scale convective disturbances propagating northeastward, from the equatorial Indian Ocean into Southeast Asia. The discussions in this entry mainly focus on the boreal winter MJO events although many aspects of these discussions can be equally applied to the boreal summer MJO events.

The MJO can be detectable in several important atmospheric and oceanic parameters, such as atmospheric cloudiness, atmospheric wind speed and direction, atmospheric temperature, atmospheric moisture, surface pressure, surface rainfall, [sea surface temperature \(SST\)](#), and surface heat and freshwater fluxes. However, the fundamental quantities related to the MJO are large-scale organized convection, cloudiness, rainfall, and tropospheric winds. Thus, our discussion of the MJO description mainly centers on how the remote sensing data help us understand the characteristics of large-scale convective cloudiness, rainfall, and tropospheric winds associated with the MJO.

Outgoing longwave radiation (OLR) and infrared window radiance (or brightness temperature) provide broadband and narrowband measures of the total flux of longwave radiation lost to space at the top of the atmosphere. Deep convective clouds in the tropics have cold cloud tops and therefore have low values of OLR and brightness temperature. Typically, an OLR value of less

than 200 W m^{-2} or a brightness temperature value of less than 220 K indicates the presence of deep convection in the tropics. Because of this simple property of OLR and brightness temperature, they have been widely used as a proxy for deep convection over the tropics, where the background longwave radiation from low clouds or surface is much higher. During the wet phase of the MJO, both OLR and window radiance can be significantly reduced due to higher and colder convective cloud tops. On the other hand, during the dry phase of the MJO, both OLR and window radiance can be significantly enhanced because of clear skies and lower and warmer cloud tops. Thus, OLR and infrared window radiance are good indicators of the convective intensity of the MJO. Over the tropical warm ocean waters where MJO convection is active, satellites are the only way to observe convective cloudiness with large spatial coverage. As a result, the satellite remote sensing data have played a central role in studying the general spatial and temporal structure and eastward-propagating features of the MJO convection and cloudiness during the past three decades.

Based on limited rawinsonde and surface station data, Madden and Julian speculated that the MJO is characterized by slowly eastward-propagating, large-scale oscillations in the tropical convective cloudiness over the equatorial Indian Ocean and western Pacific as the result of an eastward movement of large-scale atmospheric circulation cells oriented in the equatorial zonal plane. Evidence of such eastward-propagating clouds in satellite data was first presented by Arnold Gruber in 1974 and Abraham Zangvil in 1975 who both found large-scale eastward-propagating features near 40–50 days at the equator in the cloud brightness data obtained from the Environmental Science Services Administration (ESSA) satellites (ESSA 3 and 5). However, no further evidence was found until the early 1980s when NOAA OLR data and wind analyses from US National Meteorological Center (NMC) became available. These Advanced Very High Resolution Radiometer (AVHRR) OLR data started from the mid-1970s and were mainly from a series of polar-orbiting satellites, such as the scanning radiometer (SR) series and the Television Infrared Observation Satellite–Next Generation (TIROS-N) series. These OLR data have a twice-daily resolution and a good global coverage each day. By the early 1980s, almost 10 years of daily AVHRR OLR data were archived and available to the research community. In the early to mid-1980s, a series of observational papers on the MJO (at the time still referred to as the 40–50 day or 30–60 day oscillation) using the AVHRR OLR and NMC wind analyses appeared. These studies clearly demonstrated the existence of the slowly eastward propagation of the tropical cloudiness at the intraseasonal timescale and documented many detailed and important convective cloudiness and circulation features of the MJO. These papers also helped to bring the MJO to the attention of the scientific community. The NOAA polar orbiter satellites have been operating almost continuously over the

past 30 years. As a result, the NOAA OLR data have a relatively long record (over 30 years) and have been and are still extensively employed for studying the MJO.

Figure 1 shows the infrared brightness for a MJO event from December 7 to 26, 1987, with each panel separated by 5 days. Each map covers the all longitudes (0–360°) between 20°S and 20°N. Bright white areas indicate cold high clouds, and dark regions indicate cloud-free or warm low cloud conditions. The slow eastward propagation of cold high clouds associated with the MJO is evident. The cold high clouds first form over the western equatorial Indian Ocean on December 7, 1987 and, over the course of the following ~20 days, then intensify and propagate eastward across the equatorial Indian Ocean and the Maritime Continent to the equatorial western Pacific Ocean.

In addition to the large-scale eastward-propagating pattern of MJO convective cloudiness, there exist many fine-scale structures within the convective cloudiness. The high spatial (100 km) and temporal (daily) resolution AVHRR OLR data from NOAA polar orbiters and much higher spatial (a few kilometers) and temporal (3 h) resolution window-channel infrared data from the geostationary satellites, such as Geostationary Meteorological Satellite (GMS) from Japan, are particularly useful in investigating the fine structure of the MJO convective cloudiness due to their high spatial and temporal resolutions. For example, the OLR data indicated many short-period, synoptic-scale convective systems within the planetary-scale 30–60 day fluctuations. Along the equator, these active convective systems move eastward with a phase speed of 10–15 m s⁻¹ and have a horizontal spatial scale of several thousand kilometers and a timescale of less than 10 days. These synoptic-scale, eastward-propagating convective systems within the MJO envelope are referred to as super cloud clusters or more recently convectively coupled Kelvin waves. The GMS infrared window radiance data have revealed that a super cloud cluster consists of many fine-scale cloud clusters. These fine-scale cloud clusters typically propagate westward along the equator with a lifetime of about 1–2 days. Although each cloud cluster moves westward, a super cloud cluster moves eastward due to the successive formation of a new cloud cluster east of the mature-stage cloud cluster. This suggested the existence of a hierarchy of convective activity within the MJO that is still an outstanding avenue of research of today.

In the Tropics, surface rainfall is closely related to convective cloudiness and thus is another key quantity of interest to characterize the MJO. The tropical rainfall can be estimated from the satellite-observed infrared and microwave radiances. The surface rainfall can first be indirectly derived from infrared window radiance and OLR which are very sensitive to cloud-top temperatures that are indirectly tied to surface rainfall. The microwave radiances are very sensitive to the hydrometeors that directly result in surface precipitation and thus can be used more directly to retrieve surface precipitation. The microwave-based rainfall retrievals can be divided into passive and

Madden-Julian Oscillation (MJO), Figure 1 Infrared satellite observations for the global tropics (20°N–20°S) for (from the top) 03 GMT December 7, 12, 17, 22, and 26, 1987. Bright white areas indicate high clouds and deep convection, and dark regions indicate cloud-free conditions (Based on Global Cloud Imagery (GCI) data courtesy of M. Salby, University of Colorado).

active microwave (radar) retrievals. The passive retrievals can further be divided into the microwave emission-based (sensitive to cloud liquid water) and the microwave scattering-based (sensitive to ice particles and large water drops) rainfall retrievals. Starting from the 1990s, several global rainfall data have been generated from satellite-observed infrared and microwave data and were instrumental in studying the MJO during the last two decades. For example, daily, global oceanic rainfall data retrieved based on microwave emission from the Microwave Sounding Unit (MSU) on the NOAA TIROS-N satellites was first used to study the MJO convective feature in the 1990s. During the late 1990s, the NOAA Climate Prediction Center (CPC) generated a global rainfall data set, referred to CPC Merged Analysis of Precipitation (CMAP), through the merged analysis of precipitation from several sources, such as gauges, satellites, and numerical model outputs. The satellite rainfall estimates for the CMAP includes the window infrared-based rainfall estimate from NOAA geostationary satellites (e.g., Geostationary Operational Environmental Satellites, GOES), the OLR-based rainfall estimate from the NOAA polar-orbiting satellites, the microwave emission-based rainfall estimate from the MSU on the NOAA polar-orbiting

satellites and the Special Sensor Microwave/Imager (SSM/I) on the Defense Meteorological Satellite Program (DMSP) satellites, and the microwave scattering-based rainfall estimate from SSM/I. Similar merged global rainfall data were also produced by the Global Precipitation Climatology Project (GPCP) based on similar inputs. However, some subtle differences exist between the CMAP and GPCP precipitation data sets, such as diurnal cycle adjustment and atoll precipitation adjustments. Both CMAP and GPCP rainfall data with pentad (5 day) resolution have been extensively used to study the convective features of the MJO and identify MJO events. Launched in 1997, the Tropical Rainfall Measurement Mission (TRMM) satellite provided the first spaceborne precipitation radar (PR) (active microwave) to monitor global rainfall from space in addition to the passive TRMM Microwave Imager (TMI) instrument and the visible and infrared scanner (VIRS) instrument. The TRMM PR and TMI data have also been used to study the MJO. However, their spatial and temporal sampling is rather coarse. To alleviate these sampling deficiencies of the TRMM PR and TMI, the TRMM Multisatellite Precipitation Analysis (TMPA) project provides a calibration-based sequential scheme for combining precipitation estimates from multiple satellites, as well as gauge analyses where feasible, at fine scales ($0.25^\circ \times 0.25^\circ$ and 3 hourly). The input satellite data for the TMPA are mainly from two sources: (1) passive microwave-based precipitation from the TMI on TRMM, the SSM/I on DMSP satellites, the Advanced Microwave Scanning Radiometer–Earth Observing System (AMSR-E) on Aqua, and the Advanced Microwave Sounding Unit-B (AMSU-B) on the NOAA polar-orbiting satellites; (2) window infrared-based precipitation data collected by the international constellation of geostationary satellites. This TMPA data set, also known as the TRMM 3B42, has relatively better retrieval accuracy and sampling at fine spatial and temporal scales. It has been used extensively for the recent MJO studies.

In association with the eastward-propagating equatorial convective cloud and rainfall system are strong variations in lower- and upper-level large-scale atmospheric wind fields along the equator and in the subtropics. Unlike the convective cloudiness that is mostly confined over the equatorial Indian and western Pacific Oceans, the large-scale wind anomalies of the MJO extend globally along the equator and into the subtropics. For example, along the equator, low-level zonal winds converge into the convective center, while upper-level zonal winds diverge away from the convective center. These lower- and upper-level zonal winds are interconnected through ascending (upward vertical movement) moist air within the convective center and descending dry air outside the convective center. These large-scale zonal winds propagate eastward together with the convective cloudiness along the equator and can reach into the western hemisphere (eastern Pacific, Atlantic, and Africa). In addition to these zonal winds along the equator are large-scale gyre circulations extending into the subtropics in both the lower

and upper troposphere that are tied to the eastward-propagating convective cloudiness and zonal winds along the equator. For example, in the lower troposphere, a subtropical cyclonic couplet (counterclockwise in the Northern Hemisphere and clockwise in the Southern Hemisphere) flanks or lies to the west of the MJO convective region, while a subtropical anticyclonic couplet (clockwise in the Northern Hemisphere and counterclockwise in the Southern Hemisphere) lies to the east of the MJO convective region. On the other hand, in the upper troposphere, a subtropical anticyclonic couplet flanks or lies to the west of the MJO convective region, while a subtropical cyclonic couplet lies to the east of the MJO convective region due to the baroclinic nature of the tropical large-scale wind fields. The near equatorial large-scale zonal wind anomalies are a Kelvin wave response to the MJO convective heating, while the off equatorial meridional wind anomalies are a Rossby wave response to the MJO convective heating. The Kelvin wave is named after Lord Kelvin, who studied water waves along a vertical side boundary under rotation conditions. In this case, the equator, where the vertical component of the Earth's rotation vector changes sign, serves the vertical side boundary. The Rossby wave is due to the latitudinal variation of the vertical component of the Earth's rotation and is named after C. G. Rossby, who was the first to clearly isolate the so-called Rossby wave dynamics (a balance between inertia and rotation). These large-scale patterns of convective cloudiness and wind fields are components of what are collectively referred to as equatorial waves or convectively coupled equatorial waves. It is the upper-level circulation features of these waves that allow the convective signatures of the MJO over the Indo-Pacific warm pool to influence weather "downstream" over the eastern Pacific and Atlantic (e.g., hurricanes and tropical cyclones) as well as the midlatitudes (e.g., precipitation extremes along the US west coasts).

In terms of satellite observations, tropospheric winds are difficult to observe directly except via cloud tracking, such as the cloud-drift winds derived from the Multi-angle Imaging SpectroRadiometer (MISR) and NOAA geostationary satellites. However, the surface winds can be measured directly using the spaceborne radar scatterometers, such as the SeaWinds instrument on NASA's Quick Scatterometer (QuikSCAT) satellite. The importance of the cloud-drift winds and QuikSCAT surface winds for the MJO study has been recognized but still in the early stages of exploration. The overall large-scale dynamic structure of the MJO, especially in the upper levels, is still mainly derived from the global reanalyses or radiosondes at the moment.

Mechanisms

To understand the mechanisms responsible for the initiation and maintenance of the MJO, it is important to quantify the evolution of the thermodynamic environment and surface conditions associated with the MJO. In particular,

documenting the three-dimensional temperature and moisture structure of the MJO is crucial in advancing our theoretical understanding of the MJO. The availability of satellite-based temperature and moisture soundings makes these studies possible. For example, tropical mean tropospheric temperature, lower-troposphere (surface–300 mb) temperature, and upper-troposphere (500–100 mb) temperature were derived from the MSU channels in the early 1990s. These data were used to study the relationship between MJO convection and temperature anomalies in the 1990s. It was found that when the MJO is amplifying (e.g., over eastern Indian Ocean), convective heating anomalies are positively correlated to temperature anomalies. This implies production of eddy available potential energy (EAPE), which can in turn be used to drive atmospheric motion and sustain the MJO. When the MJO is decaying (e.g., over the eastern Pacific or east of the Date Line), temperature anomalies are nearly in quadrature with convective heating anomalies. As a result, their correlation and production of EAPE are small which is no longer an energy source for the MJO. For water vapor, the TIROS Operational Vertical Sounder (TOVS) provided the water vapor fields at five different levels in the troposphere in the 1990s. These data were used to study the three-dimensional structure and evolution of water vapor over the life cycle of the MJO in the early 2000s. The composite evolution of moisture shows markedly different vertical structures as a function of longitude. There is a clear westward tilt with the height of the moisture maximum associated with the MJO propagating eastward across the Indian Ocean. These disturbances evolve into nearly vertically uniform moist anomalies as they reach the western Pacific. Near-surface (below 850 mb) positive water vapor anomalies were observed to lead the convection anomaly by 5 days over the Indian Ocean and western Pacific. Upper-level positive water vapor anomalies were observed to lag the peak in the convection anomaly by 5–10 days, as the upper troposphere is moistened following intense convection. In the eastern Pacific, the moisture variations then become confined to the lower levels (below 700 mb), with upper-level water vapor nearly out of phase.

While the MSU and TOVS provided useful initial insights into the three-dimensional temperature and moisture structure of the MJO, their vertical resolution was too low to describe the detailed vertical structure, especially near the tropopause and boundary layer. Recently, global atmospheric moisture and temperature profiles with a much higher vertical resolution were produced by the Atmospheric Infrared Sounder (AIRS)/Advanced Microwave Sounding Unit on the NASA Aqua satellite. The AIRS data provide an unprecedented opportunity to document the vertical moist thermodynamic structure and spatial–temporal evolution of the MJO. Figure 2 presents the pressure–longitude cross sections of the temperature anomaly and its relationship to the convective rainfall anomaly for a composite MJO cycle (from –20 day to +20 day, separated by 10 days each). In the Indo-Pacific

warm pool, the temperature anomaly exhibits a trimodal vertical structure: a warm anomaly in the free troposphere (800–250 hPa) and a cold anomaly near the tropopause (above 250 hPa) and in the lower troposphere (below 800 hPa) for the wet phase and vice versa for the dry phase. The moisture anomaly also shows markedly different vertical structures as a function of longitude and the strength of the convection anomaly. Most significantly, the AIRS data demonstrate that, over the Indian Ocean and western Pacific, enhanced convection and precipitation is generally preceded in both time and space by a low-level warm and moist anomaly and followed by a low-level cold and dry anomaly. This zonal asymmetry in the low-level moisture and temperature anomaly provides a favorable moist thermodynamic condition for the eastward propagation of the MJO. Furthermore, the comparison between the AIRS observations and the National Center for Environmental Prediction (NCEP)/National Center for Atmospheric Research (NCAR) and NCEP/Department of Energy (DOE) reanalyses revealed the poor representation of the low-level moisture and temperature structure associated with the MJO in these reanalyses particularly over the equatorial Indian and Pacific Oceans, where there are very few conventional data to constrain the reanalyses. Despite their reliance on (imperfect) numerical models, these reanalyses have been widely used as “observations” to validate MJO theories and model simulations.

The ocean surface fluxes of heat (solar and infrared radiation, latent and sensible heat), mass (rainfall and water vapor flux), and momentum (wind) are considered important for the initiation and eastward propagation of the MJO by some researchers. Understanding the manner and degree the atmospheric components of the MJO are coupled to ocean surface fluxes is vital to understand the MJO dynamics and establish MJO theories. This coupling includes how the atmospheric components of the MJO influence the ocean surface heat, mass, and momentum fluxes and how the ocean surface provides the needed heat and moisture sources for the MJO convection. Surface heat fluxes have typically been very difficult to measure remotely from space although satellites offer the only viable way to estimate these quantities with regular temporal and spatial samplings over the tropical oceans. Apart from precipitation discussed above, satellite measurements of clouds and water vapor have been used with atmospheric radiative transfer models to provide estimates of solar and infrared radiation fluxes at the ocean surface. Moreover, satellite estimates of ocean surface winds (e.g., QuikSCAT and SSM/I discussed above) have been used in conjunction with water vapor measurements from satellites to construct estimates of latent heat (or evaporative) flux from the ocean. These types of observations, in conjunction with satellite SST retrievals (e.g., Advanced Very High Resolution Radiometer (AVHRR) or TMI), have been used to study how the MJO convection interacts with the ocean surface and explore the degree the ocean and atmosphere are coupled at intraseasonal and other

Madden-Julian Oscillation (MJO), Figure 2 Pressure-longitude cross sections of equatorial mean (averaged from 8°S to 8°N) temperature anomaly for a composite MJO cycle based on AIRS data from 2002 to 2005. The color *red* denotes warm anomalies, while the color *blue* indicates cold anomalies. The superimposed *solid black line* denotes rainfall anomaly from TRMM (Reproduced from Tian et al., 2006, their Figure 3, by permission of American Meteorological Society).

timescales. Satellite-based ocean surface wind speed observations (e.g., QuikSCAT and SSM/I discussed above) have been used to derive momentum fluxes (e.g., wind stress) at the ocean surface. These observations have been critical in documenting and understanding the role of the MJO in influencing the development and evolution of El Niño and Southern Oscillation (ENSO) events. ENSO is the most important interannual variability in the coupled tropical atmosphere ocean system with a dominant

timescale of 2–7 years and has significant impacts on the global weather and climate.

During the dry phase of the MJO, suppressed convection is associated with decreased cloud cover and increased surface insolation and anomalous surface easterlies. These anomalous surface easterlies act to decrease the surface wind speed because the background surface winds are weak westerlies in the equatorial Indian and western Pacific Oceans, hence decreasing the surface latent heat flux

Madden-Julian Oscillation (MJO), Figure 3 Geographical regions of a number of impacts of the boreal winter MJO on the global climate system. (1) Influencing tropical weather, alternative periods of wetter/drier conditions in the tropical Indian Ocean and western Pacific. (2) Modulating the diurnal cycle of tropical deep convection and rainfall in the tropical Indian Ocean and western Pacific. (3) Modulating the onsets and breaks of the Australian and South American monsoon systems. (4) Influencing ENSO cycle over the equatorial central and eastern Pacific. (5) Impacting tropical cyclone genesis over the tropical Indian Ocean and western Pacific. (6) Influencing the development of heavy rainfall events over US west coast. (7) Changing the subtropical total-column ozone over the eastern Hemisphere and Pacific Ocean. (8) Affecting the aerosol and air pollution over the equatorial Indian and western Pacific Oceans as well as the tropical Africa and Atlantic Ocean. (9) Influencing the ocean surface Chl across the tropical ocean coasts.

(or evaporation). Increased surface shortwave radiation and reduced surface evaporation contribute to the warming of SST for the dry phase. During the subsequent wet phase of the MJO, enhanced convection is associated with increased cloud cover and decreased surface insolation. As a result, the SST warming trend is arrested and a cooling trend is initiated. Subsequently, the continued cooling of the upper ocean is accelerated by increased westerly surface winds leading to enhanced surface evaporation and increased entrainment of cold water from below the thermocline. Then the wet phase is followed by another dry phase when SST warming occurs. Therefore, over the Indian Ocean and western Pacific, the enhanced convection is usually led by a warm SST anomaly to the east due to enhanced insolation and decreased evaporation and followed by a cold SST anomaly to the west due to decreased insolation and enhanced evaporation. When the convective anomaly approaches the Date Line, the surface evaporation anomaly and surface solar radiation anomaly tend to cancel each other. Thus, the SST anomaly is rather small over the eastern Pacific, so does the convective anomaly. This convection–SST phase relationship leads many scientists to believe that the MJO is a coupled mode of the tropical ocean–atmosphere system.

Impacts

During the past three decades, the MJO has been shown to have important influences on various weather and climate phenomena over the globe at many timescales, such as the diurnal cycle, tropical weather, monsoon onsets and breaks, ENSO, tropical hurricanes and cyclones, extreme precipitation events, extratropical and high-latitude circulation, and weather patterns. Given evidence that the MJO is predictable with lead times of 2–3 weeks, the strong modulation of the global climate system by the MJO implies that many

other components of the global climate system may be predictable with similar lead times. Some examples of the MJO impacts are listed and described below, and the regions of impacts are illustrated in Figure 3.

First, the MJO significantly impacts the tropical synoptic weather, such as alternative periods of wet and dry conditions, especially over the tropical Indian Ocean and west Pacific, through its influences of tropical rainfall and cloudiness (Figure 3). During the wet phase of the MJO, the tropical atmosphere is very moist and cloudy with heavy rainfall. In contrast, during the dry phase of the MJO, the tropical atmosphere experiences dry and clear conditions with plenty of sunshine.

Second, the MJO can influence the diurnal cycle of tropical deep convection and rainfall through its effect on the background state over the equatorial Indian and western Pacific oceans (Figure 3). The diurnal cycle is enhanced over both land and water during the convectively active phase of the MJO, while it is reduced during the convectively suppressed phase of the MJO. However, the diurnal phase is not significantly affected by the MJO.

Third, the MJO can substantially modulate the intensity of monsoon systems around the globe, such as the Australian and South American monsoons for boreal winter and the Asian and North American monsoons for boreal summer (Figure 3). The wet phase of the MJO can affect both the onset timing and intensity of the monsoon, while the dry phase of the MJO can prematurely end a monsoon and also initiate breaks during already existing monsoons.

Fourth, there is evidence that the MJO influences the ENSO cycle (Figure 3). It was argued that the westerly wind bursts associated with the MJO over the equatorial western Pacific are an important trigger for an El Niño event. The MJO may not cause an El Niño event, but

can contribute to the speed of development, and perhaps the overall intensity of an ENSO cycle.

Fifth, the MJO is known to modulate tropical cyclone activity in the Indian Ocean, Pacific Ocean, Gulf of Mexico, and Atlantic Ocean by providing a large-scale environment that is favorable (unfavorable) for storm development (Figure 3). For example, westerly wind anomalies at the surface in and just behind the area of enhanced convection of the MJO may generate cyclonic (anticyclonic) rotation north (south) of the equator, respectively. At the same time, in the upper levels, anticyclonic (cyclonic) rotation develops along and just behind the area of enhanced convection resulting in a means to reduce vertical wind shear and increase upper-level divergence – both of which are favorable for tropical cyclone development and intensification. The strongest tropical cyclones tend to develop during the wet phase of the MJO. As the MJO progresses eastward, the favored region for tropical cyclone activity also shifts eastward from the Indian Ocean to the Pacific Ocean and eventually to the Atlantic Ocean.

Sixth, boreal winter extreme precipitation events along the US west coast are often connected with the pattern of tropical rainfall and circulation anomalies associated with the MJO (Figure 3). When the heavy tropical rainfall associated with the MJO is concentrated at the Maritime Continent, a strong blocking anticyclone is located in the Gulf of Alaska with a strong polar jet stream around its northern flank. During this time, the US west coast typically experiences a dry spell. When the enhanced tropical rainfall associated with the MJO shifts to the central Pacific and weakens, a deep low pressure system typically forms near the Pacific Northwest coast and can bring up to several days of heavy rain and possible flooding to the Pacific Northwest coast. These events are often referred to as “Pineapple Express” events, so named because a significant amount of deep tropical moisture traverses the Hawaiian Islands on its way toward western North America.

Although most quantities/processes/phenomena of interest, such as hurricanes, monsoons, and extratropical circulation and weather patterns, are not wholly described by satellite data, the satellite-based OLR or rainfall data were usually used to identify the MJO events and often to characterize aspects of the impacts (e.g., rainfall). Some studies totally depend on the available satellite data. For example, in the study of the MJO impact on the diurnal cycle of tropical deep convection, the International Satellite Cloud Climatology Project cloud product was employed to characterize the diurnal cycle, and the TRMM 3B42 precipitation product was used to identify the MJO events.

Recently, a number of studies have documented the MJO impacts on atmospheric composition, air quality, and biogeochemical cycle. This discovery has critically depended on the availability of satellite data. For example, the MJO

impact on tropical total-column ozone has been recently characterized using the satellite-observed tropical total-column ozone from the AIRS and Total Ozone Mapping Spectrometer (TOMS). It was found that tropical total ozone intraseasonal variations are large ($\sim \pm 10$ Dobson unit) and comparable to those in the annual and interannual timescales. These intraseasonal total ozone anomalies are mainly evident in the subtropics over the Pacific and eastern hemisphere, with a systematic relationship to the MJO convection and wave dynamics discussed earlier (Figures 3 and 4a). The subtropical negative ozone anomalies typically flank or lie to the west of the equatorial anomalous convection and are collocated with the subtropical upper-troposphere anticyclones generated by the equatorial anomalous convective heating. On the other hand, the subtropical positive ozone anomalies generally lie to the east of the equatorial anomalous convection and are collocated with the subtropical upper-troposphere cyclones generated by the equatorial anomalous convective heating. The subtropical ozone anomalies are anticorrelated with geopotential height anomalies near the tropopause and thus mainly associated with the ozone variability in the stratosphere rather than the troposphere.

Another example, the recent availability of multiple, global satellite aerosol products from TOMS, Moderate Resolution Imaging Spectroradiometer (MODIS), and Advanced Very High Resolution Radiometer (AVHRR) has made the investigation of the MJO modulation of aerosols possible. Large aerosol variations are found over the equatorial Indian and western Pacific Oceans where MJO convection is active, as well as the tropical Africa and Atlantic Ocean where MJO convection is weak, but the background aerosol level is high (Figures 3 and 4b). Although significant uncertainties still exist in the satellite aerosol retrievals, the satellite data indicate that the MJO and its associated cloudiness, rainfall, and circulation variability may systematically influence the aerosol variability.

The impacts of the MJO on the carbon monoxide (CO) abundances in the tropical tropopause layer (TTL) were also recently reported based on the Aura Microwave Limb Sounder (MLS) CO data. The effects of the eastward propagation of MJO on CO abundances in the TTL are evident. This indicates that the anomalous deep convection associated with the MJO can inject CO from the lower troposphere up to the TTL.

The availability of satellite-derived ocean surface chlorophyll (Chl) from Sea-viewing Wide Field-of-view Sensor (SeaWiFS) provided a means for the discovery of the MJO impacts on oceanic biology. It was found that the MJO produces systematic and significant variations in ocean surface Chl in a number of regions across the tropical Oceans, including the northern Indian Ocean, a broad expanse of the northwestern tropical Pacific Ocean, and a number of near-coastal areas in the far eastern Pacific Ocean (Figures 3 and 4c, d). This indicates a need to further investigate the MJO modulation of the biogeochemical cycle properties and higher levels of food chains.

Madden-Julian Oscillation (MJO), Figure 4 (a) Map of total-column ozone anomaly for a composite MJO cycle based on TOMS/SBUV data from 1980 to 2006. The color red denotes high ozone anomalies, while the color blue indicates low ozone anomalies. The superimposed solid black line denotes rainfall anomaly from CMAP (Reproduced from Tian et al., 2007, by permission of American Geophysical Union). (b) As (a) but for TOMS aerosol index anomaly (Reproduced from Tian et al., 2008, by permission of American Geophysical Union). (c) As (a) but for CMAP rainfall anomalies. (d) As (a) but for SeaWiFS ocean surface Chl anomaly (Reproduced from Waliser et al., 2005, by permission of American Geophysical Union).

Summary

The MJO is a large-scale quasiperiodic oscillation of tropical atmospheric circulation and convection anomalies that moves slowly eastward along the equator mainly over the tropical Indian and Pacific Oceans with a timescale on the order of 30–60 days. The MJO is the dominant form of the intraseasonal variability in the tropical atmosphere and has many important influences on the global weather and climate system. Since the 1970s, the satellite remote sensing data have played a fundamental role in advancing our knowledge in the MJO, particularly in terms of its description, theoretical mechanisms, and global impacts. First, the satellite data provided us the fundamental knowledge of the convective and dynamic features of the MJO. Second, the satellite data presented us the three-dimensional thermodynamic structure and the surface condition (e.g., SST and surface heat flux) evolution associated with the MJO that helped us to better understand the MJO and propose theoretical description. Third, the satellite data offered us the opportunity to discover

the global impacts of the MJO that have relevance to societal concerns such as extreme precipitation events, atmospheric composition, air quality, and biological markers in the ocean.

MAGNETIC FIELD

Nils Olsen

DTU Space, Technical University of Denmark, Lyngby, Denmark

Definition

Core field. The main part of the geomagnetic field, caused by dynamo action in the Earth's fluid outer core.

Crustal field. The magnetic field contribution caused by (permanent or remnant) magnetized material in the Earth's crust.

Internal sources. Magnetic field contributions caused by electrical currents or magnetized material in the Earth's interior.

External sources. Magnetic field contributions produced by electric currents in the ionosphere or magnetosphere.

Introduction

The Earth has a large and complicated magnetic field, the major part of which is produced by a self-sustaining dynamo operating in the fluid outer core. Magnetic field observations provide one of the few tools for remote sensing the Earth's deep interior, especially regarding the dynamics of the fluid flow at the top of the core. However, what is measured at or near the surface of the Earth is the superposition of the core field and fields caused by magnetized rocks in the Earth's crust, by electric currents flowing in the ionosphere, magnetosphere, and oceans, and by currents induced in the Earth by time-varying external fields. These sources have their specific characteristics in terms of spatial and temporal variations, and their proper separation, based on magnetic measurements, is a major challenge. Such a separation is a prerequisite for remote sensing by means of magnetic field observations.

Data sources

Prior to the satellite era, only near-surface (ground-based, marine, and airborne) magnetic observations were available for magnetic probing the Earth's interior. Presently about 150 geomagnetic observatories monitor the time changes of the field; their data are available through the World Data Center system (e.g., www.ngdc.noaa.gov/wdc, www.wdc.kugi.kyoto-u.ac.jp, www.wdc.bgs.ac.uk) and INTERMAGNET (www.intermagnet.org). However, the global distribution of the observatory network is very uneven, with large uncovered areas especially over the oceans.

While observatories monitor the field change at a given fixed location, regional surveys map the magnetic field at a given epoch (short period fluctuations of external origin have to be removed from the raw data; for this purpose, measurements of the field change at a nearby observatory or a temporary station are used). However, only parts of the globe are presently covered by airborne and marine surveys. The obtained data have been used for instance in the preparation of the World Digital Magnetic Anomaly Map (WDMAM, Korhonen et al. (2007), see also <http://projects.gtk.fi/WDMAM/>) and dedicated anomaly maps like EMAG2 (Maus et al., 2009).

True global coverage with magnetic field observations is only possible with satellites. Although spaceborne probing began more than 60 years ago with the launch of the *Sputnik 3* satellite in 1958, the data coverage that is necessary for global field modeling was first obtained by the *POGO* satellite series (Cain, 2007) which measured the magnetic field intensity between 1965 and 1972. The first high-precision vector measurements from space were taken by the Magsat satellite (Purucker, 2007) in 1979–1980. More recently, the launch of the satellites Ørsted in February 1999 (Olsen, 2007), CHAMP in July 2000 (Maus, 2007), and SAC-C in November 2000 opened revolutionary new possibilities for probing the Earth from space. In the near future, the *Swarm* satellite constellation mission (Friis-Christensen et al., 2006, 2009), comprising

three satellites expected to be launched in late 2013, will provide even better possibilities for magnetic remote sensing the Earth's interior.

Characteristics of the geomagnetic field

The strength of the magnetic induction $\mathbf{B}$, in following for simplicity denoted as “magnetic field,” varies at Earth's surface between about 25,000 nT near the equator and about 65,000 nT near the poles ($1 \text{ nT} = 10^{-9} \text{ T}$, with $1 \text{ T} = 1 \text{ tesla} = 1 \text{ V/s}^{-1} \text{ m}^{-2}$). By far the largest part (95 % or more at Earth's surface) is due to dynamo action in the core (e.g., Roberts, 2007); magnetized material in the crust (e.g., Purucker and Whaler, 2007) accounts on average for only a few % of the total field but can locally reach magnitudes of several hundreds or even thousands of nT. Crustal magnetization consists of two parts: *Induced magnetization* is proportional, both in strength and direction, to the ambient field within which the rock is embedded. Were the core field to disappear, induced magnetization would vanish, too. Then, only the second type of magnetization, *remnant magnetization*, remains. As a general rule, remnant magnetization is weak in continental regions (where induced magnetization dominates), while both types of magnetizations are significant in oceanic areas.

The top panel of Figure 1 shows the magnetic field intensity at Earth's surface in 2010.0, and the middle panel shows the yearly change in field intensity (also for epoch 2010.0), based on the International Geomagnetic Reference Field (IGRF) (Finlay et al., 2010). Core and crust contribute to all spatial scales of the field, but the core field dominates for horizontal scales larger than 2,800 km (corresponding to spherical harmonic degrees $n < 14$) while the crustal field dominates for horizontal scales smaller than 2,800 km ($n > 14$). The bottom panel of the figure shows the crustal anomaly field (scales smaller than 2,400 km) close to the surface (4 km above the geoid), based on the EMAG2 model of Maus et al. (2009). The crustal field is static (at least on timescales of centuries or shorter), but the core field undergoes a significant time change, known as secular variation. The temporal change shown in the middle panel of Figure 1 is therefore caused by processes in the Earth's core.

In addition to these internal sources, there are contributions from electric currents in the ionosphere (90–1,000 km altitude) and the magnetosphere (at distance larger than several Earth radii); these are called external sources. They are very dynamic, ranging from a few nT during geomagnetic quiet conditions to several hundreds or even thousands of nT during disturbed times, with especially large amplitudes at polar latitudes. Figure 2 shows a typical spectrum of the magnetic North component for a site at mid-latitudes. Time changes with periods longer than 4 years are dominated by core processes, while those at shorter periods, and especially signals with seasonal and daily periodicity, are caused by ionospheric and magnetospheric sources. See Schmucker (1985) for details on the

Magnetic Field, Figure 1 Earth's magnetic field intensity (*top*) and its time change (*middle*) in 2010, at Earth's surface. *Bottom*: intensity of magnetic field anomalies at 4 km altitude above the geoid.

external field variations ELF, sferics, ULF, pulsations, DP, Dst, and Sq. These short period changes, which are caused by external currents, produce secondary, induced, currents in the Earth's interior, the magnetic field of which adds to that of the primary, external, currents. The observed magnetic time variations are thus a superposition of primary (inducing) and secondary (induced) contributions. Analysis of these time changes

Magnetic Field, Figure 2 Amplitude of magnetic field variations (*north component*) at middle latitudes in dependence on period, determined using data from the sites Socorro/USA (1 ms to 1 s), Kakioka/Japan (2 s to 2 h), and Niemegk/Germany (longer than 2 h). Note that the pre-Maxwell approximation Equation 1 is only valid for periods $\gg 1$ s.

provides information on the electrical conductivity of the Earth's interior (e.g., Constable, 2007).

Although field changes of internal as well as external origin occur at all timescales, a common practice in separating them relies on their different temporal variations. Over the last 150 years, the axial dipole component of the Earth's magnetic field has decayed by nearly 10 %. This is ten times faster than the natural decay, in case the dynamo was switched off. The current decay rate is characteristic of magnetic reversals, which – as paleomagnetic data have shown – occur on average about once every half million years. Geographically, the recent dipole decay is largely due to changes in the field beneath the South Atlantic Ocean, connected to the growth of the South Atlantic anomaly. The core field and its temporal change (secular variation) directly reflect the fluid flow in the outermost core and provide a unique observational constraint on geodynamo theory. However, only the part of the core field that varies on timescales longer than, say, 1 year is

observable at the Earth's surface; shorter fluctuations are heavily attenuated due to the electrical conductivity of the mantle. Hence, variations with timescales longer than a few years are usually attributed to processes in the core, whereas those with periods shorter than 1 year are attributed to external field contributions. Yet interesting features occur at intermediate timescales. A serious limitation regarding the investigation of core processes at timescales of months to years is the effect of geomagnetic variations of external origin, since they contribute significantly on timescales up to that of the 11 year solar cycle.

Basic equations

Magnetic field investigation of core and crust is typically done in the quasi-static approximation, which requires that the timescales in consideration are longer ($\gg 1$ s) compared to the time required for light to pass the length scale of interest ($< a$ few thousand kilometers). In this so-called

pre-Maxwell approximation, displacement currents can be neglected, and the magnetic field $\mathbf{B}$ is given by

$$\nabla \times \mathbf{B} = \mu_0 \mathbf{J} \quad (1)$$

where $\mu_0 = 4\pi 10^{-7}$ Vs/(Am) is vacuum permeability and current density

$$\mathbf{J} = \mathbf{J}_e + \mathbf{J}_m \quad (2)$$

(expressed in units of A/m²) is the sum of free-charge current density $\mathbf{J}_e$ and the equivalent current density, $\mathbf{J}_m = \nabla \times \mathbf{M}$, due to material of magnetization $\mathbf{M}$ (units of A/m). The sources of magnetic fields are therefore electric currents (for instance, in the Earth's core, the ionosphere or the magnetosphere) and/or magnetized material (for instance, in the Earth's crust).

Outside its sources (i.e., in regions with $\mathbf{J} = 0$), the magnetic field, $\mathbf{B} = -\nabla V$, is a Laplacian potential field and can be derived from a scalar magnetic potential V . In that case, the magnetic field has similar properties as the gravity field and the same methods for studying both fields might be used (Blakely, 1995). However, the similarity is only true under certain assumptions.

While near-surface magnetic field measurements are compatible with the potential assumption (since electric currents are negligible in the atmosphere and thus the data are obtained in a source-free region), the situation is different for spaceborne observations: Satellites probing the Earth's magnetic field typically fly at altitudes between 300 and 1,000 km in the ionospheric F -region, and especially at polar latitudes, the occurrence of local electric currents violates the assumption of a current-free data-sampling region. Satellite magnetic field data therefore cannot be described by a Laplacian potential field alone. Strategies for handling satellite data are discussed for instance in Hulot et al. (2007), Olsen et al. (2010), and Sabaka et al. (2010).

Applications of magnetic remote sensing

There are three main aspects of probing the Earth's interior using magnetic field observations.

Firstly, the dynamics of fluid flow at the top of the core can be determined from observations of the core field and its time change. This is a nonunique problem which requires assumptions on the flow dynamics, for instance to be steady or purely horizontal (i.e., toroidal). In addition to the fundamental nonuniqueness, the fact that only the slowly varying large-scale part of the core field is observable (periods shorter than a few months are heavily attenuated when propagating through the electrically conducting mantle and thus not observable at the surface, and the small-scale part of the core field is masked by the crustal field) puts additional limitations on the fraction of core flow that can be determined. Nevertheless, the magnetic field has proven to provide an extremely useful (and the only) tool to probe core flow. Recent overviews

on this subject are given by Holme (2007) and Whaler (2007).

Secondly, information on the structure, composition, and temperature of the crust can be obtained from investigations of the crustal magnetic field. Its small-scale part, mapped by regional near-surface surveys, provides information on shallow geological structures useful to petroleum and mineral exploration, while the long-wavelength part (up to 2,800 km – longer scales are masked by the core field) is a valuable tool to investigate the lower crust and upper mantle. See Langel and Hinze (1998), Purucker and Whaler (2007), and Ravat (2007) for more details on crustal field studies.

Finally, observations of the time-changing part of the magnetic field (of periods between seconds and several days) form the basis for electromagnetic induction studies, providing information on the electrical conductivity of the crust and mantle. The obtained conductivity distribution gives insight into geodynamic processes. This is complementary to seismic remote sensing since conductivity reflects the connectivity of constituents such as fluids, partial melt, and volatiles (all of which may have influence on rheology, mantle convection, and tectonic activity), while seismology ascertains bulk mechanical properties. A description of the techniques for probing the conductivity of the Earth's interior, and examples of obtained results, is given for instance in Constable (2007).

Conclusions

Magnetic field observations provide one of the few tools for remote sensing the Earth's interior, especially regarding the dynamics of core fluid flow and the structure, composition, and temperature of the crust. In addition, studying time variations of the magnetic field allows for determination of the electrical conductivity of the crust and mantle.

MEDIA, ELECTROMAGNETIC CHARACTERISTICS

Yang Du

Zhejiang University, Hangzhou, People's Republic of China

Definition

Media, electromagnetic characteristics. Macroscopic permittivity and permeability properties of media.

Introduction

When electromagnetic wave propagates in some medium other than vacuum, since the characteristic wavelength is several orders larger than the atoms of which the medium is composed, the detailed behavior of the fields over atomic distance becomes irrelevant. What do matter are the quantities averaged over the atomic scale, including the macroscopic fields and macroscopic sources. Such treatment implies that the inhomogeneous medium is essentially replaced by a homogeneous one with macroscopic permittivity and permeability (Jackson, 1998).

Macroscopic properties

In macroscopic media, the electric displacement field **D** and magnetic field **H** are related to the electric field **E** and magnetic induction **B** through the macroscopically averaged electric dipole, magnetic dipole, electric quadrupole, and higher-order multipoles. In most materials, only the electric and magnetic polarizations are significant.

In an isotropic medium, the constitutive relations are **D** = ϵ **E**, and **B** = μ **H**, where ϵ and μ are the permittivity and permeability, respectively. A diamagnetic medium has μ larger than μ_0 , since diamagnetic substance, whose atoms or molecules have no angular momentum, creates induced magnetic moments that tend to oppose the applied magnetic field. A paramagnetic medium has μ smaller than μ_0 , since paramagnetic substance has a net angular momentum which is aligned parallel to the applied magnetic field.

For anisotropic media, the constitutive relations are **D** = $\bar{\epsilon}$ **E** and **B** = $\bar{\mu}$ **H**, where $\bar{\epsilon}$ and $\bar{\mu}$ are the permittivity and permeability tensor, respectively. Crystals are generally characterized by symmetric permittivity tensors, which can be transformed into a diagonal matrix as

$$\bar{\epsilon} = \begin{bmatrix} \epsilon_x & 0 & 0 \\ 0 & \epsilon_y & 0 \\ 0 & 0 & \epsilon_z \end{bmatrix}$$

When $\epsilon_x = \epsilon_y = \epsilon_z$, the crystals are isotropic, such as the cubic crystals. Uniaxial crystals have two of the three parameters equal. Examples are tetragonal, hexagonal, and rhombohedral crystals (Kong, 2005).

For bianisotropic media, the constitutive relations are **D** = $\bar{\epsilon}$ **E** + $\bar{\zeta}$ **H** and **B** = $\bar{\zeta}$ **E** + $\bar{\mu}$ **H** (Kong, 2005).

Dispersion

All media are dispersive in that the phase velocity of a wave depends on the frequency. That is, waves with different frequencies travel in a dispersive medium at different speeds. The frequency dependence of ϵ and μ leads to new effects when an arbitrary wave train containing a range of frequencies travels.

What enter the picture of dispersion are the molecular constitution of matter and the dynamics of molecules. A simple model leads to a dispersion formula which in most cases serves as an adequate representation of the dielectric constant as a function of frequency. The success of this model is truly amazing considering the several assumptions being made, including treating the relative permeability equal to unity, neglecting magnetic force effects, and confining the oscillation to be sufficiently small. The forces exerting upon an electron include an electric force due to the electric field, a restoring force, and a damping force. The resultant formula for the dielectric constant is

$$\epsilon(\omega) = \epsilon_0 + \frac{Ne^2}{m} \sum_k \frac{v_k}{\omega_k^2 - \omega^2 - i\omega\gamma_k},$$

where $-e$ and m are the charge and mass of an electron, respectively. Here it is assumed that there are N molecules per unit volume and v_k electrons per molecule with binding frequency ω_k and phenomenological damping constant γ_k (Jackson, 1998).

When real part of $\epsilon(\omega)$ increases with ω , it is called normal dispersion. Anomalous dispersion refers to the reverse. Since in general the resonant frequencies ω_k are large compared to the damping factors γ_k , in the neighborhood of ω_k , the behavior of $\epsilon(\omega)$ is expected to be rather violent, with disruption of the normal dispersion and appearance of appreciable imaginary part of $\epsilon(\omega)$ or resonant absorption.

At frequencies far beyond the highest resonant frequency, the dielectric constant is simply expressed in terms of the plasma frequency ω_p of the medium as $\epsilon(\omega) \approx \epsilon_0 - \frac{\omega_p^2}{\omega^2} \epsilon_0$.

The Kramers-Kronig relations or dispersion relations are simple integral formula relating the real part to imaginary part of the complex permittivity $\epsilon(\omega)$ or a dispersive process to an absorption process. The validity of these relations is very general due to the fact that very few assumptions are made, among which are the monochromatic components of the displacement $\mathbf{D}(\mathbf{r}, \omega)$ and the electric field $\mathbf{E}(\mathbf{r}, \omega)$ at position $\mathbf{r}$ related by $\mathbf{D}(\mathbf{r}, \omega) = \epsilon(\omega)\mathbf{E}(\mathbf{r}, \omega)$, as well as a causality requirement on the kernel relating $\mathbf{D}(\mathbf{r}, t)$ and $\mathbf{E}(\mathbf{r}, t)$. The wide generality of the dispersion relations makes them very useful in all areas of physics (Toll, 1956). For instance, in the scattering of nuclear particles, these relations connect real and imaginary parts of the diagonal elements of the scattering matrix (Jost et al., 1950).

Inhomogeneous composite

A macroscopically inhomogeneous medium is a typical representation of many materials. For instance, a snow pack is a composite of ice particles and water; a porous rock is a composite of the rock matrix and salt water if the latter is present. In each example, the medium possesses spatially varying quantities such as permittivity and conductivity.

Electromagnetic characterization of inhomogeneous composite materials is important in a wide variety of applications, such as in astronomy and atmospheric physics and selective absorbers of solar and infrared radiation.

In the effective medium approximation of Bruggeman and Landauer, a composite of two components is considered. To obtain the effective conductivity of this composite, each particle is imagined to be immersed in a homogeneous effective medium of conductivity σ_e instead of in its actual inhomogeneous medium. The self-consistency condition is invoked such that the average electric field within a particle shall equal the electric field far from the particle. In essence, in the effective-medium approximation, only electron-dipole scattering contributes. The characteristic particle dimension in the composite is required to be small compared to the characteristic wavelength. If a two-component composite has one component dominant in volume fraction, then both approaches work well. However, it is found that EMA produces significant error in far-infrared absorption by a composite composed of dielectric and small metal particles with concentrations below the percolation threshold (Stroud, 1998).

A self-consistency condition is to choose an effective dielectric constant such that for particles embedded in the medium, on the average, their forward scattering amplitude should vanish (Stroud and Pan, 1978). Generalization to continuous size distribution of particles as well as arbitrary number of components is provided in Chylek and Srivastava (1983), where both the contribution of electric and magnetic dipole terms are considered. Special attention is paid to a composite material where small metallic particles are among the components. The form of the size distribution of metallic particles is found to determine the critical volume fraction at which there is a drastic absorption increase.

Metamaterial

Metamaterial is a new class of artificially constructed electromagnetic material that can exhibit electromagnetic properties difficult or impossible to find in conventional materials (Pendry, 2004; Smith et al., 2004). For example, the material property of negative index of refraction has been realized at both GHz and optical frequencies using metamaterial concepts.

Recent advances in construction of metamaterial with independent and arbitrary varying capability of

permittivity and permeability values pave the way for totally new electromagnetic phenomena. For instance, the electric displacement $\mathbf{D}$, the magnetic field intensity $\mathbf{B}$, and the Poynting vector $\mathbf{S}$, by controlling the material electromagnetic properties, can be directed at will, made focused, or avoid objects. In particular is the design of cloaking of objects from electromagnetic fields (Pendry et al., 2006).

Summary

In macroscopic media, the electric displacement field and magnetic induction can be related to the electric intensity and magnetic intensity in ways quite different from that in vacuum. With increasing complexity, the medium can be characterized as isotropic, anisotropic, and bianisotropic. All media are dispersive in that the phase velocity of a wave depends on the frequency. The real and imaginary parts of the frequency-dependent complex permittivity are related by the Kramers-Kronig relations, which are very useful in all areas of physics. In characterizing the electromagnetic properties of an inhomogeneous medium, the effective-medium approximation is useful within its region of validity. Beyond that, the method base on the self-consistency condition can be employed. In terms of artificial materials, metamaterial is a new class of artificially constructed electromagnetic material that can exhibit electromagnetic properties difficult or impossible to find in conventional materials, which leads to totally new electromagnetic phenomena.

MICROWAVE DIELECTRIC PROPERTIES OF MATERIALS

Martti Hallikainen
Aalto University, Espoo, Finland

Synonyms

Dielectric constant; Permittivity

Definitions

Permittivity characterizes the electrical properties of materials: The real part gives the contrast with respect to vacuum and the imaginary part gives the electromagnetic loss of the material. Loss tangent is defined as the imaginary part divided by the real part of permittivity. Total electromagnetic loss in a medium consists of absorption loss (electromagnetic power transformed into other forms of energy, such as heat) and scattering loss (energy is caused to travel in directions other than that of incident radiation). Penetration depth provides an approximate value to the maximum depth of the medium that contributes to the backscattering coefficient and brightness temperature. Optical depth between two points in a medium provides a measure of how transparent the medium is to electromagnetic power passing through it. Both the real and imaginary parts of the permittivity of water are very large compared to other natural media; hence, the dielectric properties of water tend to dominate those of materials containing water.

Basic electromagnetic quantities for describing materials

Several basic electromagnetic quantities are defined in order to characterize the microwave interaction with matter. Two electrical quantities, electric flux density and electric field intensity, constitute a fundamental pair of electromagnetic fields, and they are related via

$$\vec{D} = \epsilon \epsilon_0 \vec{E} \quad (1)$$

where $\vec{D}$ is the electric flux density (displacement) vector, $\vec{E}$ is the electric field vector, ϵ is the relative (compared to vacuum) permittivity, and $\epsilon_0 = 8.854 \times 10^{-12}$ As/V/m is the vacuum permittivity. The permittivity of free space (air) is equal to that of vacuum with a high degree of accuracy.

Relative permittivity and loss tangent

The relative permittivity is a complex number and is denoted by

$$\epsilon = \epsilon' - j\epsilon'' \quad (2)$$

where $j = \sqrt{-1}$. It characterizes the electrical properties of materials: The real part (ϵ') gives the contrast with respect to free space ($\epsilon'_{air} = 1$), and the imaginary part (ϵ'') gives the electromagnetic loss of the material. The real

and imaginary parts of ε are often referred to as the dielectric constant and the dielectric loss factor, respectively. The loss tangent, defined as

$$\tan(\delta) = \frac{\varepsilon''}{\varepsilon'} \quad (3)$$

may also be used to characterize the loss of materials.

Propagation, absorption, and phase constant

For an electromagnetic plane wave traveling in the z -direction, the intensity of the electric field at point z can be expressed as

$$E(z) = E_0 e^{-\gamma z} \quad (4)$$

where E_0 is the field intensity at $z = 0$. The complex propagation constant of the medium is denoted by γ and is expressed as

$$\gamma = \alpha + j\beta \quad (5)$$

where α is the absorption constant and β is the phase constant. The absorption constant describes transformation of wave energy into other forms of energy, such as heat. The phase constant is equal to the wave number $k = 2\pi/\lambda$, where λ is wavelength, in a lossless medium. α and β are related to the complex permittivity by

$$\alpha = k_0 |\text{Im}\{\sqrt{\varepsilon}\}| \quad (6)$$

$$\beta = k_0 \text{Re}\{\sqrt{\varepsilon}\} \quad (7)$$

where k_0 is the wave number in free space.

Power absorption coefficient

The power absorption coefficient κ_a is defined as

$$\kappa_a = 2\alpha \quad (8)$$

and is often expressed in dB/m through the relation

$$\kappa_a(\text{dB/m}) = 8.686 \alpha (\text{Np/m}) \quad (9)$$

Extinction and scattering coefficient

The total electromagnetic loss in a medium consists of absorption loss (electromagnetic power transformed into other forms of energy, such as heat) and scattering loss (energy is caused to travel in directions other than that of the incident radiation). Scattering loss is caused by particles of different ε embedded in a host medium. The extinction coefficient (total loss) is thus

$$\kappa_e = \kappa_a + \kappa_s \quad (10)$$

where κ_s denotes the scattering loss.

Penetration depth

Part of a wave incident upon the surface of a medium from the air in the direction z is transmitted across the boundary

into the medium. The penetration depth δ_p is defined as the depth z at which (Ulaby et al., 1986)

$$\frac{P(z = \delta_p)}{P(z = 0+)} = \frac{1}{e} \quad (11)$$

where $P(\delta_p)$ is the transmitted power at depth δ_p and $P(0+)$ is the transmitted power just beneath the surface. If scattering in the medium is ignored, $\kappa_e \equiv \kappa_a = 2\alpha$ and if, additionally, α is constant as a function of z ,

$$\delta_p = \frac{1}{\kappa_a} = \frac{\sqrt{\varepsilon'}}{k_0 \varepsilon''}; \quad \varepsilon'' \ll \varepsilon' \quad (12)$$

The penetration depth provides an approximate value to the maximum depth of the medium that contributes to the backscattering coefficient and brightness temperature.

Optical depth

The optical depth between two points r_1 and r_2 in a medium provides a measure of how transparent the medium is to electromagnetic power passing through it. It is defined as

$$\tau(r_1, r_2) = \int_{r_1}^{r_2} \kappa_e dr \quad (13)$$

The optical depth is often used in atmospheric remote sensing.

Dielectric properties of natural media

The first book on the dielectric properties of materials was published by Debye, who presented his theory on polar liquids in 1929. Von Hippel published, in 1954, his book on theoretical and experimental aspects of dielectric media. The two-volume analysis of electric polarization was published by Böttcher (1973) and Böttcher et al. (1978). Followed by progress in microwave remote sensing in the 1970s, both theoretical and experimental studies of the dielectric properties of natural media increased rapidly. Electromagnetic mixing theories were analyzed by Sihvola (1999).

Electromagnetically, pure water is homogeneous matter, because its characteristics are not a function of the position within water. It is also isotropic, meaning that its characteristics are the same in all directions. However, most natural media are either nonhomogeneous or anisotropic; they may be mixtures of various substances, possibly with certain geometry. For example, soils consist of soil solids particles, air voids, and water. Seawater contains a variety of dissolved salts, making its dielectric behavior different from that of pure water. An example of anisotropic media is sea ice, which consists of ice, air, and mostly vertical brine inclusions.

In microwave remote sensing, interaction of electromagnetic waves with matter is modeled using the macroscopic dielectric properties of targets. Due to the

complex structure of many natural media, their dielectric characteristics cannot be derived theoretically with a sufficiently high degree of accuracy. Hence, the dielectric models for most media are semiempirical, relying on both theoretical studies and measurements made under laboratory conditions. In the following, the dielectric properties of natural media essential in microwave remote sensing are discussed. Various mixing models for computing the bulk dielectric properties of natural media are presented.

Most natural media contain water. Since the complex permittivity of water is substantially larger than that of other natural media at frequencies relevant to microwave radiometer and radar remote sensing, the dielectric properties of water tend to dominate those of other media including soils, vegetation, snow, and ice. The volumetric water content in soils, especially clay, may be up to 50 %, in vegetation parts up to 70 %, and in snow over 10 %. The permittivity of most natural dry materials is small ($\epsilon' < 5$ and $\epsilon'' < 0.1$). The dielectric properties of pure water, freshwater, and seawater are discussed first in this presentation, followed by those of other natural media important for microwave remote sensing.

Dielectric properties of pure water, freshwater, and seawater

Pure Water. For polar liquids like water, the complex permittivity can be derived by assuming that a polar molecule interacts with an electromagnetic field by rotating in a viscous medium. This results in the so-called Debye equation for water (Debye, 1929):

$$\epsilon_w = \epsilon_{w\infty} + \frac{\epsilon_{w0} - \epsilon_{w\infty}}{1 + j2\pi f\tau_w} \quad (14)$$

where ϵ_{w0} is relative permittivity of water in a static electric field, $\epsilon_{w\infty}$ is relative permittivity of water at an “infinitely high” frequency, τ_w is relaxation time of water, and f is frequency. ϵ'_w and ϵ''_w depend, in addition to frequency, on temperature. The real and imaginary part of permittivity can be solved from (Equation 14):

$$\epsilon'_w = \epsilon_{w\infty} + \frac{\epsilon_{w0} - \epsilon_{w\infty}}{1 + (2\pi f\tau_w)^2} \quad (15a)$$

$$\epsilon''_w = \frac{2\pi f\tau_w(\epsilon_{w0} - \epsilon_{w\infty})}{1 + (2\pi f\tau_w)^2} \quad (15b)$$

Numerical expressions for the terms of (Equation 14) as a function of temperature and salinity are available in Klein and Swift (1977); these equations have been regularly used for computing the complex permittivity of seawater. The frequency at which the maximum dielectric loss occurs is called the relaxation frequency; it is given by

$$f_0 = \frac{1}{2\pi\tau_w} \quad (16)$$

It has been recently concluded that the model based on the Debye relaxation process (Equation 14) is accurate to within less than 1 % up to 30 GHz at temperatures around 25 °C, but differences between the extrapolated value and independently measured permittivity values are about 10 % at 90 GHz (Ellison, 2006).

There are two approaches to increase accuracy at frequencies beyond 30 GHz and at low temperatures, the double Debye model of Liebe et al. (1991) and the extended double Debye model of Ellison (2006). The double Debye model is basically the same as that given in (Equation 14), but it includes two relaxation processes instead of one (Liebe et al., 1991):

$$\epsilon_w = \frac{\epsilon_{w01} - \epsilon_{w\infty1}}{1 + j\left(\frac{f}{f_{01}}\right)} + \frac{\epsilon_{w\infty1} - \epsilon_{w\infty2}}{1 + j\left(\frac{f}{f_{02}}\right)} + \epsilon_{w\infty2} \quad (17)$$

where ϵ_{w01} is the static permittivity, f_{01} and f_{02} are the first and second relaxation frequency, respectively, and $\epsilon_{w\infty1}$ and $\epsilon_{w\infty2}$ are the first and second high-frequency permittivity, respectively, and

$$\theta = 1 - \frac{300}{T(K)} \quad (18)$$

$$\epsilon_{w01} = 77.66 - 103.3\theta \quad (19)$$

$$\epsilon_{w\infty1} = 0.0671\epsilon_{w01} \quad (20)$$

$$f_{01} = 20.20 + 146.4\theta + 316\theta^2 \quad (21)$$

$$\epsilon_{w\infty2} = 3.52 + 7.52\theta \quad (22)$$

$$f_{02} = 39.8f_{01} \quad (23)$$

where $T(K)$ is the temperature in Kelvins.

Based on the double Debye model in (Equations 17–23), Figure 1 shows the complex permittivity of pure water over the frequency range of 100 MHz–1,000 GHz for temperatures between 10 °C and 50 °C.

Freshwater. There are relatively few dissolved ions in freshwater, and hence, ϵ' for freshwater is practically the same as that for pure water. However, the loss term must be corrected by adding a conductivity term:

$$\epsilon''_{iw} = \epsilon''_w + \frac{\sigma}{2\pi f\epsilon_0} \quad (24)$$

where subscript i refers to freshwater (impure water) and σ is the conductivity. Due to the frequency term in the denominator of (Equation 24), the effect of conductivity increases with decreasing frequency.

Pure Water and Seawater. Seawater contains dissolved salts, including NaCl, MgCl₂, Na₂SO₄, CaCl₂, and KCl, and the average salinity in the oceans is 32.5 psu (Anderson, 1960). Dissolved salts in seawater increase the ionic conductivity. Consequently, the dielectric loss factor of seawater is substantially higher than that of pure water at low microwave frequencies.

Microwave Dielectric Properties of Materials, Figure 1 Complex dielectric permittivity of pure water according to Liebe et al. (1991).

For this reason, L-band is optimal for retrieval of ocean salinity from radiometer data.

Recently, the dielectric behavior of water has been approximated using an extended double Debye model up to 25 THz for pure water and up to 105 GHz for seawater (Ellison, 2006). His results are based on several data sets and indicate that there are three relaxation processes in the microwave region and two resonances in the far-infrared region. At 25 °C, the relaxation frequencies are 18.56 GHz, 167.83 GHz, and 1.944 THz; the two resonance frequencies are 4.03 and 14.48 THz. Freshwater and seawater contain dissolved ions and gases; hence, their dielectric behavior is different from that of pure water. Using the extended double Debye model, the complex permittivity is then expressed (Ellison, 2006) as

$$\epsilon_w = \epsilon_{w\infty} + \frac{\epsilon_{w0} - \epsilon_{w1}}{1 + j2\pi f \tau_{w1}} + \frac{\epsilon_{w1} - \epsilon_{w\infty}}{1 + j2\pi f \tau_{w2}} - j \frac{\sigma_w}{2\pi f \epsilon_0} \quad (25)$$

The parameters ϵ_{w0} , ϵ_{w1} , $\epsilon_{w\infty}$, τ_{w1} , τ_{w2} , and σ_w depend on temperature and salinity of water. Their highly complex numerical expressions are given in (Ellison, 2006, pp. 445–454):

$$\epsilon_s(T, S) = 87.85306 \exp(-0.00456992T - a_1S - a_2S^2 - a_3ST) \quad (26)$$

$$\epsilon_1(T, S) = a_4 \exp(-a_5T - a_6S - a_7ST) \quad (27)$$

$$\tau_1(T, S) = (a_8 + a_9S) \exp\left(\frac{a_{10}}{T + a_{11}}\right) \quad (28)$$

$$\tau_2(T, S) = (a_{12} + a_{13}S) \exp\left(\frac{a_{14}}{T + a_{15}}\right) \quad (29)$$

$$\epsilon_{\infty}(T, S) = a_{16} + a_{17}T + a_{18}S \quad (30)$$

$$\sigma(T, S) = \sigma(T, 35) \cdot P(S) \cdot Q(T, S) \quad (31)$$

where

$$\sigma(T, 35) = 2.903602 + 8.607 \cdot 10^{-2}T + 4.738817 \cdot 10^{-4}T \quad (32)$$

$$- 2.991 \cdot 10^{-6}T^3 + 4.3041 \cdot 10^{-9}T^4 \quad (33)$$

$$P(S) = S \frac{37.5109 + 5.45216S + 0.014409S^2}{1,004.75 + 182.283S + S^2} \quad (34)$$

and

$$Q(T, S) = 1 + \frac{\alpha_0(T - 15)}{T + \alpha_1} \quad (35)$$

where

$$\alpha_0 = \frac{6.9431 + 3.2841S - 0.099486S^2}{84.85 + 69.024S + S^2} \quad (36)$$

$$\alpha_1 = 49.843 - 0.2276S + 0.00198S^2 \quad (37)$$

Equations 25–37 with Table 1 are stated to represent the permittivity of pure water to within 1 % over the frequency range 0–20 GHz, to within 3 % over the frequency range 30–100 GHz, and to within 5 % over the frequency range 100–1,000 GHz (Ellison, 2006). The permittivity of seawater is represented to within 3 % over the frequency

Microwave Dielectric Properties of Materials, Table 1 Coefficients for Equations 26–30

$a_1 = 0.46606917$ E (–2)	$a_7 = 0.34414691$ E (–4)	$a_{13} = 0.38957681$ E (–6)

range 3–105 GHz within temperatures of 0–30 °C and salinities of 0–40 psu. Below 3 GHz, the results of Klein and Swift (1977) can be used.

Dielectric properties of snow

Dry Snow. Dry snow consists of ice crystals and air voids. Any water in the snow medium collects at points of contact between the ice grains. The metamorphism caused by melting and freezing changes the microstructure of snow. The ice grains become rounded during the melting process and some of the smaller grains disappear completely. Snow that has undergone several melt–freeze cycles tends to form multiple clusters. In general, the density of snow slowly increases with time due to metamorphism and melt–freeze cycles. The density of dry snow varies from 0.1 g/cm³ (newly fallen snow) to 0.5 g/cm³ (refrozen snow).

Since dry snow is a dielectric mixture of ice and air, its complex permittivity is governed by the dielectric properties of ice, snow density, and ice-particle shape. Since the real part of the permittivity of ice is $\varepsilon'_i = 3.17$ at frequencies between 10 MHz and 1,000 GHz (Mätzler and Wegmüller, 1987) and practically independent of temperature, the dielectric constant of dry snow, ε'_{ds} is only a function of density. For the most extensive data set used in dielectric measurements of snow, the result between 3 and 37 GHz is (Hallikainen et al., 1986)

$$\varepsilon'_{ds} = 1 + 1.9 \rho_{ds}; \quad \rho_{ds} \leq 0.5 \text{ g/cm}^3 \quad (38)$$

where ρ_{ds} is the density of dry snow in g/cm³. From (Equation 38), $\varepsilon'_{ds} = 1.57$ for a density of 0.3 g/cm³. A piecewise linear relationship between ε'_{ds} and ρ_{ds} has been reported based on measurements at 1 GHz and related modeling (Mätzler, 1996).

Experimental data for the loss factor of dry snow are limited to frequencies below 13 GHz (Cumming, 1952; Tiuri et al., 1984). The best fit to the experimental data of Tiuri et al. was provided by the following expression:

$$\varepsilon''_{ds} = 1.59 \cdot 10^6 (0.52 \rho_{ds} + 0.62 \rho_{ds}^2) \cdot \left(f^{-1} + 1.23 \cdot 10^{-14} \sqrt{f} \right) \exp(0.036T) \quad (39)$$

where T is the temperature in °C and f is the frequency in Hz. An alternative equation has been provided by Ulaby et al., (1986) using a two-phase dielectric mixing formula for spherical inclusions. Both approaches indicate that the dielectric loss factor of dry snow has a minimum value between 1 and 5 GHz and then increases with increasing frequency. It is of the order of 10^{-4} – 10^{-3} at all frequencies below 100 GHz; hence, dry snow is a loss–loss medium.

Due to its granular structure, dry snow is a strongly scattering medium at high microwave frequencies. Based on theoretical calculations using the Mie theory (assuming independent scattering), scattering dominates over absorption in dry snow (ice grain size 1 mm) at frequencies above 15 GHz (Ulaby et al., 1986). Scattering loss increases rapidly with increasing frequency; hence, the extinction coefficient at and above 35 GHz consists mainly of scattering loss. Based on an extensive data set of snow samples ranging from newly fallen to refrozen snow, with the ice grain diameter ranging from 0.2 to 1.6 mm and snow density from 0.17 to 0.39 g/cm³, the following empirical expressions have been developed to relate the extinction coefficient of dry snow, denoted κ_{eds} , to the observed snow particle diameter d_s (Hallikainen et al., 1987):

$$\kappa_{eds} = 1.5 + 7.4 d_s^{2.3} \text{ dB/m at 18 GHz} \quad (40)$$

$$\kappa_{eds} = 30 d_s^{2.1} \text{ dB/m at 35 GHz} \quad (41)$$

$$\kappa_{eds} = 180 d_s^{2.0} \text{ dB/m at 60 GHz} \quad (42)$$

$$\kappa_{eds} = 300 d_s^{1.9} \text{ dB/m at 90 GHz} \quad (43)$$

The particle diameter (observed by photography) is in millimeters. Equations 40–43 hold for particle sizes below 1.6 mm. Equations 40–42 can be combined into a single equation of the form

$$\kappa_{eds} = 0.0018 f^{2.8} d_s^{2.0} \text{ dB/m} \quad 18 \text{ GHz} < f < 60 \text{ GHz} \quad (44)$$

where f is in GHz and d_s is in mm. Due to the exponent value of 2.8 in (Equation 44), the extinction coefficient increases rapidly with increasing frequency; at 35 GHz it is about 20 dB/m for snow with a grain size of 1 mm, whereas at 90 GHz it is well over 100 dB/m. This is why radiometers operating at 35 GHz are able to measure snow water equivalents less than 100 mm and those operating at 90 GHz “see” only the snowpack surface. The strong fluctuation theory (Stogryn, 1986) provides results that agree reasonably well with the empirical extinction coefficient values in the 18–60 GHz range for all realistic grain sizes and also at 90 GHz for grain sizes smaller than 0.9 mm.

Wet Snow. Wet snow is a mixture of ice crystals, liquid water, and air. The geometry and porosity of wet snow depend on its liquid water content. It has been concluded that snow has two distinct regimes of liquid saturation (Colbeck, 1982). In the lower range (pendular regime), air is continuous throughout the pore space, and liquid water occurs in the form of isolated inclusions. In the higher range of liquid saturation (funicular regime), liquid water is continuous throughout the pore space, and air occurs as distinct bubbles trapped by narrow constrictions in the pores. There is a sharp transition between the two regimes.

Electromagnetically, wet snow is a three-component dielectric mixture consisting of ice particles, air, and liquid water. Both water and ice exhibit Debye-type relaxation spectra. The relaxation frequency (frequency at which the maximum dielectric loss occurs) of ice is in the kilohertz range, whereas that for water at 0 °C is 9 GHz. The complex permittivity of ice and water depends on frequency and temperature. Consequently, the permittivity of wet snow is a function of frequency, temperature, volumetric water content, snow density, ice-particle shape, and the shape of water inclusions.

Since the permittivity of water is substantially higher than that of ice and air, the dielectric behavior of wet snow is governed by the volume fraction of water. Basically, ϵ'_{ws} and ϵ''_{ws} are compressed versions of those for water at 0 °C. The dielectric behavior of wet snow was measured by Hallikainen et al. (1986) at nine frequencies between 3 and 18 GHz and, additionally, at 37 GHz. They tested four dielectric models: Debye-like model, modified Debye-like model, two-phase Polder–Van Santen model (Polder and Van Santen 1946), and three-phase Polder–Van Santen model. The two-phase Polder–Van Santen mixing formula is applied by assuming wet snow to consist of dry snow as the host material with water inclusions embedded in it. The shape of the water inclusions was included in the modeling study. Tiuri et al. (1984) used a resonator in the 0.5–1 GHz range and also the 4 GHz data set of Hallikainen et al. (1982) and developed a numerical model for the permittivity of wet snow. Mätzler et al. (1984) made resonator measurements at 1 GHz and applied their results for spectral modeling of wet snow. See Hallikainen et al. (1986) for a review of dielectric wet snow studies.

The samples of Hallikainen et al. (1986) had densities ranging from 0.09 to 0.42 g/cm³ and liquid water contents ranging from 0 % to 12.3 % by volume. The snow particle size varied between 0.5 and 1.5 mm and the sample temperatures ranged from –5 °C to 0 °C. The two-phase Polder–Van Santen model for wet snow is

$$\epsilon_{ws} = \epsilon_{ds} + \frac{m_v \epsilon_{ws}}{3} (\epsilon_w - \epsilon_{ds}) \cdot \sum_{j=1}^3 [\epsilon_{ws} + (\epsilon_w - \epsilon_{ws}) A_{wj}]^{-1} \quad (45)$$

where m_v is the volumetric liquid water content and water droplets are randomly distributed and randomly oriented

ellipsoids with depolarization factors A_{w1} , A_{w2} , and A_{w3} . The general Debye-like model is expressed as

$$\epsilon'_{ws} = A + \frac{Bm_v^x}{1 + (f/f_0)^2} \quad (46a)$$

$$\epsilon''_{ws} = \frac{C(f/f_0)m_v^x}{1 + (f/f_0)^2} \quad (46b)$$

where f_0 is the relaxation frequency (9.07 GHz) and A , B , C , and x are constants determined by fitting the model to the measured data in the 3–37 GHz range. The obtained values are given in Hallikainen et al. (1986). In the simplified Debye-like model, A , B , and C depend only on dry snow density and volumetric water content, whereas in the modified Debye-like model, they depend, additionally, on frequency. The Debye-like equations do not take into account the geometry of the wet snow medium (shape of water inclusions, funicular and pendular regimes).

Liquid water inclusions in snow are approximately needle shaped in the pendular regime (low values of water content), but they become approximately disk shaped in the funicular regime (high values of water content) (Colbeck, 1982). The best fit of the developed two-phase Polder–Van Santen mixing model to experimental data was obtained by assuming that their shapes depend on snow water content and, additionally, that the water inclusions are nonsymmetrical in shape (Hallikainen et al., 1986). Transition from the pendular regime to the funicular regime was observed to take place around snow volumetric water content $m_v = 3$ %.

Both the modified Debye-like model and the two-phase Polder–Van Santen model (with variable, nonsymmetrical shape factors) provide good accuracy (Hallikainen et al., 1986). The simplified Debye-like model works well only at frequencies below 15 GHz, but the modified Debye-like model works well also at higher frequencies. The two-phase Polder–Van Santen model with wetness-dependent shape factors provides a slightly better overall fit to the experimental observations of wet snow. The modified Debye-like model is easier to use and is likely to provide adequate accuracy for most applications. The three-phase Polder–Van Santen model provided accuracies comparable to those of the two-phase Polder–Van Santen model.

The real part of the dielectric constant of wet snow varies from the values for dry snow up to 3.0 at 3 GHz and to 1.9 at 37 GHz for a liquid water content of 12 % and, generally, decreases with increasing frequency. Its dielectric loss factor increases with frequency until it reaches its maximum value of 0.9 at 9 GHz for a wetness of 12 %. At frequencies above 9 GHz, it decreases monotonically. Even a volumetric water content of 2 % results in absorption of tens of decibels per meter, depending on frequency. The penetration depth for wet snow is generally less than 20 cm at frequencies above 5 GHz, suggesting that microwave radar and radiometer measurements can provide information only on the top of the snowpack.

Dielectric properties of ice

Pure and Freshwater Ice. Freshwater ice is free from salt, but usually it includes air bubbles, impurities, and cracks. Pure ice is an idealization of freshwater ice (frozen distilled water); it is not discussed here. The dielectric properties of freshwater ice at microwave frequencies are determined by two physical processes, namely, the high-frequency tail of a relaxation spectrum (relaxation frequency in the kilohertz range) and the low-frequency tail of far-infrared absorption bands (Evans, 1965; Mätzler and Wegmüller, 1987). These processes result in a practically constant value for the dielectric constant ϵ'_i at microwave frequencies and in a minimum of the dielectric loss factor ϵ''_i centered around 1–5 GHz.

Based on experimental data, the relative dielectric constant of pure and impure ice may be assigned the constant value of

$$\epsilon'_i = 3.17 \quad (47)$$

for frequencies between 10 MHz and 100 GHz (Mätzler and Wegmüller, 1987; Cumming, 1952).

For the imaginary part of the permittivity, results of various investigators show substantial scatter. The scatter is caused, in addition to measurement inaccuracies (partly due to small values of ϵ''_i), by varying amounts of impurities in the ice samples. Reviews of results are available, for example, in Ulaby et al. (1986). A numerical equation for ϵ''_i was developed by Mätzler and Wegmüller (1987):

$$\epsilon''_i = \frac{A}{f} + Bf^C \quad (48)$$

where f is the frequency in GHz. The values of constants A , B , and C were determined for pure and impure ice at temperatures -5°C and -15°C . The values for impure ice at -5°C are $A = 0.0026$, $B = 0.00023$, and $C = 0.87$. For pure ice, they are $A = 0.0006$, $B = 0.000065$, and $C = 1.07$. For -15°C , they are for impure ice $A = 0.0013$, $B = 0.00012$, and $C = 1.0$. For pure ice, they are $A = 0.00035$, $B = 0.000036$, and $C = 1.2$. Based on (Equation 41), ϵ''_i for impure ice is between 0.001 and 0.01 in the 1–100 GHz range and slightly smaller for pure ice. Thus, freshwater ice is a low-loss medium, and its power absorption coefficient at 1 GHz (temperature -5°C) is about 0.1 dB/m and penetration depth is 100 m. At 10 GHz, the corresponding numbers are about 1 dB/m and 10 m. This means that contributions to the brightness temperature and the backscattering coefficient are not limited to the topmost ice layers.

Sea Ice. Sea ice consists of freshwater ice, liquid brine, and air. In addition to the dielectric properties of these constituents, several additional parameters influence its complex permittivity, including the volume fraction of each constituent and geometry (shape, size, and orientation) of brine pockets with respect to the propagation direction of the electromagnetic wave. Most of these parameters depend on ice temperature. The salinity of liquid brine in

sea ice is governed by its temperature, and it is over 200 ‰ by weight at -20°C and decreases to about 35 ‰ at -2°C (Assur, 1960). The relative volume of liquid brine is directly proportional to the salinity; for sea ice with a salinity of 1 ‰, it is about 3 ‰ at -20°C , 24 ‰ at -2°C , and 103 ‰ at -0.5°C (Frankenstein and Garner, 1967). Due to the high volumetric content and salinity, the complex permittivity of brine is substantially higher than that of seawater (Stogryn and Desargant, 1985). Hence, brine characteristics dominate the permittivity of sea ice.

Experimental investigations of the microwave dielectric behavior of sea ice have been carried out at frequencies below 40 GHz. Reviews of these investigations are given in Vant (1976) and Hallikainen and Winebrenner (1992). The total number of permittivity measurements for arctic ice is small. Additionally, most of the investigations are limited to first-year ice. Frequency-wise, extensive sets of experimental Arctic sea ice data were acquired by Vant (1976), Vant et al. (1978) (0.1–7.5 GHz; 13 samples), and Sackinger and Byrd (1972) (26–40 GHz; sample number not reported). Sample-wise, the most extensive studies are those of Bogorodskii and Khokhlov (1975) (10 GHz; 130 samples) and Hallikainen (1983) (0.6 and 0.9 GHz; 373 samples). References Vant (1976) and Vant et al. (1978) report the same results, but the former includes detailed results for each ice sample. Hoekstra and Cappillino (1971) (0.1–24 GHz) measured ice samples of various salinities, made from seawater flash frozen in a sample holder; their results have very likely been influenced by sample preparation technique.

In most studies, temperatures below -5°C were used, although rapid changes in the permittivity occur at temperatures close to 0°C due to increasing relative volume of brine. Hallikainen (1983) measured low-salinity ($S < 2$ ‰) ice samples at temperatures up to -0.1°C . In order to avoid brine drainage, each ice sample was measured immediately after removing it from the ice field and using only the original temperature. The relative brine volume of low-salinity sea ice near 0°C may be higher than that of high-salinity sea ice at lower temperatures. The relative brine volume of sea ice of salinity 1 ‰ is 103 ‰ at -0.5°C , whereas the corresponding number for sea ice of salinity 4 ‰ is 40 ‰ at -5°C .

A limited amount of data is available on the dielectric properties of multiyear sea ice (Vant, 1976, two samples; Vant et al., 1978, two samples). Due to lower salinity, the complex permittivity of multiyear ice is lower than that of first-year ice.

Only Vant et al. (1978) (NaCl ice; orientation from vertical 0° , 30° , 45° , 60° , and 90°), Sackinger and Byrd (1972) (Arctic first-year ice; 0° and 90°), and Hallikainen (1983) (low-salinity first-year ice; 0° , 30° , and 90°) have investigated the effect of sample orientation with respect to the propagation direction of the electromagnetic wave. Sackinger and Byrd (1972) observed that the dielectric loss factor at -7°C may be up to 300 % higher for 90° (horizontal orientation) than for 0° (vertical); it decreases

with decreasing temperature and is about 150 % higher at -21.5°C . Hence, the dielectric loss of sea ice increases with increasing incidence angle. Based on their data, Vant et al. (1978) developed a model to account for sample orientation. The permittivity also depends on ice type; in general, the dielectric loss is higher for frazil than for columnar sea ice with the electromagnetic wave propagating in the vertical direction.

Comparisons between various data sets have shown that there is substantial scatter for values of both the real part and imaginary part of the permittivity for mostly used frequencies like 1 GHz, 5 GHz, and 10 GHz (Hallikainen and Winebrenner, 1992). Efforts to model the dielectric behavior of sea ice are scarce. Vant et al. (1978) used two approaches based on the relative brine volume and a semiempirical approach to account for the orientation. Stogryn (1987) employed strong fluctuation theory to compute the tensor dielectric constant for sea ice. Hallikainen and Winebrenner (1992) generated numerical equations, based on available data sets, to relate the dielectric properties of sea ice to the relative brine volume V_b at three frequencies – 1 GHz, 4 GHz, and 10 GHz. Their expressions are given below in a slightly modified form, due to revisiting the data sets.

$$\varepsilon'_{si} = 3.12 + 0.009 V_b; \quad 1 \text{ GHz} \quad (49a)$$

$$\varepsilon''_{si} = 0.04 + 0.005 V_b; \quad 1 \text{ GHz} \quad (49b)$$

$$\varepsilon'_{si} = 3.05 + 0.007 V_b; \quad 4 \text{ GHz} \quad (50a)$$

$$\varepsilon''_{si} = 0.02 + 0.0033 V_b; \quad 4 \text{ GHz} \quad (50b)$$

$$\varepsilon'_{si} = 3.04 + 0.004 V_b; \quad 10 \text{ GHz} \quad (51a)$$

$$\varepsilon''_{si} = 0.01 + 0.007 V_b; \quad 10 \text{ GHz} \quad (51b)$$

where the relative brine volume $V_b \leq 70\%$ and is given by (Frankenstein and Garner, 1967):

$$V_b = S \left(-\frac{52.56}{T} - 2.28 \right) \quad -0.5^{\circ}\text{C} \geq T \geq -2.06^{\circ}\text{C} \quad (52a)$$

$$V_b = S \left(-\frac{45.917}{T} + 0.930 \right) \quad -2.06^{\circ}\text{C} > T \geq -8.2^{\circ}\text{C} \quad (52b)$$

$$V_b = S \left(-\frac{43.795}{T} + 1.189 \right) \quad -8.2^{\circ}\text{C} > T \geq -22.9^{\circ}\text{C} \quad (52c)$$

Equations 49a, b–51a, b do not explicitly take into account the effect of ice density upon the real part of the permittivity or direction of wave propagation in the ice medium. The correlation coefficient for Equations 49a, b–51a, b is, in general, between 0.7 and 0.8.

In general, the absorption coefficient κ_a increases with increasing frequency and temperature. The loss of multiyear ice is considerably lower than that of first-year ice, mainly due to much lower salinity. The values for first-year low-salinity sea ice show that the temperature dependence of the absorption coefficient is high at temperatures near 0°C . At 10 GHz, the differences between the results for columnar, frazil, and multiyear ice are substantial.

In the 1–10 GHz range, the penetration depth is between 100 and 5 cm for first-year ice and 500 and 30 cm for multiyear ice. Sensors operating at X-band provide information on sea ice mainly from the topmost 5–80 cm, depending on ice type, salinity, and temperature, whereas the corresponding numbers for L-band sensors are 40–500 cm.

Dielectric properties of soils

Soils consist of bulk soil, air, and water. A soil's textural composition is usually given in terms of weight percentages of sand, silt, and clay. Sand includes particles with diameters in the range between 0.05 and 2.0 mm, silt includes particles with diameters in the 0.002–0.05 mm range, and clay includes particles with diameters smaller than 0.002 mm. The water contained in the soil is usually divided into bound water and free water, although the transition between these is not sharp. Molecules of bound water are contained in the first few molecular layers surrounding the soil particles; these are tightly held by the soil particles due to the matric and osmotic forces (Baver et al., 1977). The amount of bound water is proportional to the total surface area of the soil particles, which depends on the soil particle size distribution and mineralogy: The smaller the particles, the more there can be bound water. Hence, clay has more bound water than sand. Water molecules located further away from the soil particle surface can move within the soil medium and are referred to as free water.

From the electromagnetic point of view, soil is a heterogeneous medium consisting of bulk soil, air, bound water, and free water. Its dielectric properties as a function of frequency depend on the soil bulk density (compaction), soil composition (particle size distribution and mineralogy), the volume fractions of bound and free water, the salinity of the soil solution, and temperature (Dobson et al., 1985). Wang and Schmugge (1980) showed that various dielectric mixing formulas describing soil as a two-component system (soil with free water) fail to describe the complex permittivity of wet soil realistically at 1.4 and 5 GHz. They were the first to explicitly include both free water and bound water in their empirical mixing formula by examining two moisture regions: (a) water contents less than the maximum bound water fraction and (b) water contents higher than the bound water fraction. They included two free parameters in the model and, by optimizing their values, were able to explain the behavior of the complex permittivity, especially its real part. Wang (1980) modeled the soil–water system with

a Debye-like relaxation over a finite band of relaxation frequencies and, by adjusting two free parameters, adequately predicted the behavior of data over the 0.3–1.4 GHz range. The two free parameters were the width of the activation energy of the soil solution and the mean relaxation frequency of the soil–water mixture at a given frequency and for a given soil and water content.

Hallikainen et al. (1985) performed dielectric measurements of five soil types at 12 frequencies between 1.4 and 18 GHz. Soil moisture values from 0 % to the highest moisture contents that can be supported by that soil type without drainage taking place were used; additionally, data for frozen soils were acquired as well. They developed for each frequency polynomial expressions, separately for real and imaginary parts of the permittivity, dependent on volumetric moisture content and the percentage of sand and clay contained in the soil. Dobson et al. (1985) developed two dielectric models for wet soil based on the data set of Hallikainen et al. (1985), a theoretical model and a semiempirical model. The theoretical model accounts explicitly for the presence of bound water adjacent to hydrophilic soil particle surfaces and employs a four-component dielectric mixing model that describes the soil–water system consisting of dry soil solids as a host medium with randomly distributed and randomly oriented disc-shaped inclusions of bound water, bulk water, and air. The bulk water component characteristics in the model depend on frequency, temperature, and salinity. Based on comparisons with data, the theoretical model was determined to be an appropriate formulation, and it yields values that describe well the observed effects of frequency and soil type. However, its accuracy is limited by the uncertainty concerning the dielectric properties of bound water.

The driving force in the development of the semiempirical model of Dobson et al. (1985) was to develop a user-friendly, frequency-dependent model that is based on readily measured soil characteristics including volumetric moisture and weight fractions of sand and clay. The final expressions for the real and imaginary parts of the permittivity are

$$\epsilon'_{ws} = \left[1 + \frac{\rho_b}{\rho_s} (\epsilon_s^\alpha - 1) + m_v^{\beta'} \epsilon_{fw}^{\alpha'} - m_v \right]^{\frac{1}{\alpha}} \quad (53a)$$

$$\epsilon''_{ws} = \left[m_v^{\beta''} \epsilon_{fw}^{\alpha''} \right]^{\frac{1}{\alpha}} \quad (53b)$$

where α is a constant shape factor, ρ_b is soil bulk density, $\rho_s = 2.66 \text{ g/cm}^3$ is soil specific density, ϵ_s is the soil solid permittivity, m_v is the volumetric moisture, β' and β'' are the soil-texture-dependent coefficients for computing the real and imaginary part, respectively, and ϵ_{fw} is the permittivity of free water. The optimum value for the shape factor was determined to be $\alpha = 0.65$. The relative permittivity of soil solids is

$$\epsilon_s = (1.01 + 0.44\rho_s)^2 - 0.062 \quad (54)$$

and the soil-texture-dependent coefficients are

$$\beta_{\epsilon'} = 0.01(127.48 - 0.519S - 0.152C) \quad (55a)$$

$$\beta_{\epsilon''} = 0.01(1.33797 - 0.603S - 0.166C) \quad (55b)$$

where S and C are the percentage of sand and clay, respectively. The dielectric properties of free water are computed using an expression similar to that for saline water:

$$\epsilon_w = \epsilon_{w\infty} + \frac{\epsilon_{w0} - \epsilon_{w\infty}}{1 + j2\pi f \tau_w} - j \frac{\sigma_{eff}}{2\pi f \epsilon_0} \cdot \frac{\rho_s - \rho_b}{\rho_s m_v} \quad (56)$$

where the effective conductivity is

$$\sigma_{eff} = -1.645 + 1.939\rho_b - 0.02013S + 0.01594C \quad (57a)$$

The above expressions were determined using the whole soil dielectric data set between 1.4 and 18 GHz. For the frequency range of 0.3–1.3 GHz, another expression for the effective conductivity was developed (Peplinski et al., 1995):

$$\sigma_{eff} = 0.0467 + 0.2204\rho_b - 0.4111S + 0.66144C \quad (57b)$$

For a reader interested in the dielectric properties of soils at a certain frequency between 1.4 GHz and 18 GHz, the polynomial expressions in Hallikainen et al. (1985) are useful. Mironov et al. (2004) developed a generalized refractive index mixing dielectric model for moist soils incorporating the dielectric characteristics of bound water.

The above studies show that the complex permittivity of wet soil is a compressed version of that for slightly saline water. In the 1.4–18 GHz range, the real part of the permittivity increases with increasing volumetric moisture and decreasing frequency, whereas the imaginary part increases with increasing moisture and increasing frequency. At any given moisture content and at all frequencies, the real part is roughly proportional to sand content and inversely proportional to clay content; however, this effect decreases with increasing frequency. The effect of soil texture on the imaginary part varies with frequency. At 1.4 GHz, the real part increases with increasing clay content for moisture levels above $0.2 \text{ cm}^3/\text{cm}^3$, whereas at 4–6 GHz, it is nearly independent of soil texture at all moisture levels and at frequencies of 8 GHz and above it decreases with increasing clay content. This behavior is obviously due to the ionic conductivity (strongest at low frequencies) and the relation of volume fraction of bound water to soil specific surface. At moisture levels close to saturation, ϵ may reach values up to 23-j3 for sand ($m_v = 0.35$) and 33-j9 for clay ($m_v = 0.50$) at 1.4 GHz. At 18 GHz, the corresponding values are 13-j8 and 18-j12, respectively. The penetration depth for wet soil decreases drastically with increasing moisture content and frequency;

consequently, retrieval of soil moisture from microwave radiometer and radar data works best at low frequencies. Even at 1.4 GHz, information only on surface moisture is obtained.

The permittivity of soils decreases drastically at temperatures below 0 °C (Hallikainen et al., 1985). Between −11 °C and −24 °C, both the real and imaginary parts of permittivity still depend on temperature, demonstrating that not all water is frozen. Recently, Mironov et al., (2010) conducted dielectric measurements on organic rich permafrost soil from 1 to 16 GHz and from −30 °C to +25 °C. They also extended the previously developed dielectric soil model of Mironov et al. (2004) to cover frozen soil.

Dielectric properties of vegetation

The characteristics of plants and trees vary substantially, including the size, density, moisture content, and geometry. Hence, the physical characteristics of vegetation material are not discussed in this presentation. For a detailed discussion on timber characteristics, the reader is referred to Dinwoodie (2000). Dielectric properties of wood are discussed in detail in Torgovnikov (1993); they have been primarily examined for industrial purposes, especially for microwave drying of timber at 2.45 GHz.

The dielectric properties of plants including trunks, stalks, and leaves for remote sensing have been measured and modeled by El-Rayes and Ulaby (1987), and Ulaby and El-Rayes (1987) in the 0.2–20 GHz range, and monitored in situ at L-band by McDonald et al. (1999). Mätzler (1994) measured and modeled various leaves at frequencies 1–94 GHz. Ulaby et al. (1987) measured the propagation constant for vegetation canopies with vertical stalks between 1.6 and 10.2 GHz. Dielectric spectroscopy of Scots pine at frequencies up to 1 GHz has been done by Tomppo et al. (2009).

Ulaby and El-Rayes (1987) modeled the complex permittivity of vegetation as a simple additive mixture of plant material, free water, and bound water due to their observation that bound water has a substantially lower relaxation frequency than free water. At 22 °C, their Debye–Cole dual-dispersion model for the permittivity of vegetation is

$$\begin{aligned} \varepsilon_v = \varepsilon_r + v_{fw} \left[4.9 + \frac{75.0}{1 + j \cdot 0.556f} - j \frac{18\sigma}{f} \right] \\ + v_{bw} \left[2.9 + \frac{55.0}{1 + (j \cdot 0.556f)^{0.5}} \right] \end{aligned} \quad (58)$$

where ε_r is the permittivity of bulk vegetation material, f is the frequency in GHz, σ is the ionic conductivity of the free-water solution in S/m, and v_{fw} and v_{bw} are the relative fractions of free and bound water, respectively. The volumetric moisture content consists of free water and bound water:

$$M_u = v_{fw} + v_{bw} = \frac{M_g \rho}{1 - M_g(1 - \rho)} \quad (59)$$

where M_g denotes the gravimetric moisture content and ρ is the bulk density. If M_g and ρ are known, the following expressions can be used for obtaining higher accuracy:

$$\varepsilon_r = 1.7 + 3.2M_v + 6.5M_v^2 \quad (60)$$

$$v_{fw} = M_v(0.82M_v + 0.166) \quad (61)$$

$$v_{bw} = \frac{31.4M_v^2}{1 + 59.5M_v^2} \quad (62)$$

The Debye–Cole dual-dispersion model has been determined to provide an estimate of ε'_v for leaves, stalks, branches, and trunks with an accuracy of 5 %. If the salinity S is known in order to provide an estimate for the conductivity (S/m) via

$$\sigma = 0.16S - 0.0013S^2 \quad (63)$$

similar accuracies apply to ε''_v .

Summary

Dielectric properties of natural media at microwave frequencies have been reviewed, and the effects of various physical parameters to the behavior of their permittivity have been discussed. Since most natural media are heterogeneous, theoretical derivation of their dielectric properties is not straightforward. Measurements provide useful information for model development and evaluation, but only within the range of the covered physical characteristics and employed frequencies. The permittivity of pure and saline water is the key to modeling the behavior of most natural media; gaps still occur for its values at near-freezing temperatures, especially at high microwave frequencies. More experimental data are needed to confirm the behavior of wet snow at frequencies above 18 GHz. Measurements of the permittivity of sea ice for various salinities and ice types, especially for high brine volumes and at temperatures above −5 °C, would substantially benefit modeling of the behavior of sea ice. Permittivity measurements of various types of vegetation are needed to test presently available semiempirical models and further develop them.

MICROWAVE HORN ANTENNAS

Yahya Rahmat-Samii

Department of Electrical Engineering, University of California at Los Angeles, Los Angeles, CA, USA

Definition

Horn Antenna. An antenna with metallic flare walls which provides a transition between waves propagating in a waveguide and electromagnetic waves directivity radiated into space.

Microwave horn antennas

Horns are one of the simplest and most widely used microwave antennas. Interests in horn antennas date back to the turn of the nineteenth century and then considerably revived during World War II. Microwave horn antennas are essentially a device to make a transition from waves propagating in a waveguide into electromagnetic signals transmitting in another open medium such as free space. They can have metallic walls, dielectric material, or the combination of both, and occur in various shapes and sizes to fulfill many practical applications, such as communication systems, remote sensing, radio frequency heating, reference sources for other antenna testing and evaluation. Other than being a stand-alone directive power transmitter/receiver, horns are also used as feeds for other antennas such as reflectors, lenses, and compound antennas. Their widespread application is due to their simple, solid geometry and excellent performance when beam directivity is required (Love, 1976; Balanis, 1988, 1996; Olver et al., 1994; Bird and Love, 2007).

Figure 1 summarizes the primary categories of horns, and Figure 2 shows some representative examples of well-known horn designs. Rectangular pyramidal horns

are probably the most commonly used class of horns. One of the primary applications of a pyramidal horn is the standard gain antenna since its gain may be calculated very accurately by knowing their dimensions. The beamwidths in the two principal planes can also be independently controlled by varying the rectangular-aperture dimensions. Some other forms of rectangular horns with nonlinear profiles are also used to increase aperture efficiency and lower side lobes compared with a linear flare. Circular geometries are also in widespread use. The axial symmetry of conical horns allows them to generate any polarization of the dominant mode which makes them well suited for circular polarization. The beamwidths, however, are usually unequal in the two principal planes. In order to overcome this problem, the dual-mode and corrugated (hybrid-mode) conical horns have been developed. Higher-order modes are excited so that the aperture field of the horn is modified in such a way as to produce radiation patterns with axial symmetry and very low cross-polarization.

Horn specifications

Ample types of horns can provide various radiation performances, and for every specific application, it is necessary for an antenna designer to consider some critical specifications which dictate the choosing of an appropriate type of horn antennas.

Bandwidth

The frequency band over which the system is to operate is usually specified as a range of frequencies (for single-band applications) where the antenna must satisfy a required return loss (or VSWR) and provide a radiation pattern adequate for the application. Consider an antenna required to operate from $f_{\min}$ to $f_{\max}$. The bandwidth, in general, can be calculated as

Horn Antennas		
Rectangular	Circular	Other Types
Smooth wall	Smooth-wall conical	Diagonal
Corrugated	Corrugated	Elliptical
Dielectric-lined	Scalar	Dielectric
Profiled	Dielectric-lined	
Multimode	Coaxial	
Ridged	Profiled	
	Longitudinal corrugation	
	Multimode	
	Ridged	

Microwave Horn Antennas, Figure 1 A summary of primary types of horn antennas.

Microwave Horn Antennas, Figure 2 Representative types of horn antennas: (a) pyramidal horn, (b) circular horn, and (c) corrugated horn.

$$\text{Bandwidth (\%)} = \frac{2(f_{\max} - f_{\min})}{(f_{\max} + f_{\min})} \times 100.$$

Based on this definition, a bandwidth below 20 % is generally considered narrowband whereas a bandwidth over 20 % is considered wideband. Often, there is a specific frequency determined in specifications as the design frequency at which the design provides optimum performances. For single-band applications, a practical choice is a design frequency of $f_c = \sqrt{f_{\min} \cdot f_{\max}}$ for narrowband operations and $f_c = 1.2 f_{\min}$ for wideband operations.

Gain and aperture efficiency

The antenna gain takes into account both the directional capability and efficiency of the antenna. Among many different types of gains, two definitions are usually used to describe horn antennas (Balanis, 1996). The most commonly accepted definition of gain only considers the accepted power and removes the power reflected from the input. In this definition, an ideal horn without losses is assumed and the gain equals directivity as the efficiency is 100 %. Another definition, called absolute gain, retains the reflected power from the input, as this is an intrinsic property of the antenna. For horn antennas, the results of these two definitions are usually very similar since the reflection coefficient is small. The difference is a factor of $1/(1 - |\Gamma_{\text{in}}|^2)$, where Γ_{in} is the reflection coefficient at the input.

Another useful measure for comparing the performances of horn antennas is the aperture efficiency. It is defined as the ratio of the antenna gain in the direction (θ, ϕ) and the gain of the same antenna aperture with ideal uniform illumination given by

$$\eta_{\text{aperture}} = \frac{\lambda^2}{4\pi A} G(\theta, \phi),$$

where A is the total area of the aperture, λ is the wavelength at the operating frequency, and $G(\theta, \phi)$ is the gain function. In many applications it is assumed that the aperture efficiency is in the boresight direction of the antenna.
